MAXIMUM POWER POINT TRACKING CONTROLLERS AND ASSOCIATED SYSTEMS AND METHODS

BACKGROUND

Photovoltaic cells produce a voltage that varies with current, cell operating condition, cell physics, cell defects, and cell illumination. One mathematical model for a photovoltaic cell, as illustrated in FIG. 1, models output current as:

$$I = I_L - I_0 \left\{ \exp \left[\frac{q(V + IR_S)}{nkT} \right] - 1 \right\} - \frac{V + IR_S}{R_{SH}} \quad \text{EQN. 1}$$

Where

I_L =photogenerated current

R_S =series resistance

R_{SH} =shunt resistance

I_0 =reverse saturation current

n =diode ideality factor (1 for an ideal diode)

q =elementary charge

k =Boltzmann's constant

T =absolute temperature

I =output current at cell terminals

V =voltage at cell terminals

For silicon at 25° C., $kT/q=0.0259$ Volts.

Typical cell output voltages are low and depend on the band gap of the material used to manufacture the cell. Cell output voltages may be merely half a volt for silicon cells, far below the voltage needed to charge batteries or drive most other loads. Because of these low voltages, cells are typically connected together in series to form a module, or an array, having an output voltage much higher than that produced by a single cell.

Real-world photovoltaic cells often have one or more microscopic defects. These cell defects may cause mismatches of series resistance R_S , shunt resistance R_{SH} , and photogenerated current I_L from cell to cell in a module. Further, cell illumination may vary from cell to cell in a system of photovoltaic cells, and may vary even from cell to cell in a module, for reasons including shadows cast by trees, bird droppings shadowing portions of a cell or module, dust, dirt, and other effects. These mismatches in illumination may vary from day to day and with time of day—a shadow may shift across a module during a day, and rain may wash away dust or dirt shadowing a cell.

From EQN. 1, output voltage is greatest at zero output current, and output voltage V falls off nonlinearly with increasing output current I . FIG. 2 illustrates the effect of increasing current drawn from a photovoltaic device at constant illumination. As current I is increased under constant illumination, voltage V falls off slowly, but as current I is increased to an output current near the photocurrent I_L , output voltage V falls off sharply. Similarly, cell power, the product of current and voltage, increases as current I increases, until falling voltage V overcomes the effect of increasing current, whereupon further increases in current I drawn from the cell cause power P to decrease rapidly. For a given illumination, each cell, module, and array of cells and modules therefore has a maximum power point (MPP) representing the voltage and current combination at which output power from the device is maximized. The MPP of a cell, module, or array will change as temperature and illumination, and hence photogenerated current I_L , changes. The MPP of a cell, module, or

2

array may also be affected by factors such as shadowing and/or aging of the cell, module, or array.

Maximum Power Point Tracking (MPPT) controllers for operating a photovoltaic cell at or near its maximum power point have been proposed. These controllers typically determine an MPP voltage and current for a photovoltaic device connected to their input, and adjust their effective impedance to maintain the photovoltaic device at the MPP. However, conventional MPPT controllers often have one or more drawbacks. For example, some proposed MPPT controllers may be relatively slow under certain conditions, thereby delaying MPP operation.

SUMMARY

In an embodiment, a maximum power point tracking controller includes an input port for electrically coupling to an electric power source, an output port for electrically coupling to a load, a control switching device, and a control subsystem. The control switching device is adapted to repeatedly switch power from the input port to the output port. The control subsystem is adapted to control switching of the control switching device to regulate a voltage across the input port, based at least in part on a signal representing current flowing out of the output port, to maximize a signal representing power out of the output port.

In an embodiment, an electric power system includes an electric power source and a maximum power point tracking controller. The maximum power point tracking controller includes an input port electrically coupled to the electric power source, an output port for electrically coupling to a load, a control switching device, and a control subsystem. The control switching device is adapted to repeatedly switch between its conductive and non-conductive states to transfer power from the electric power source to the output port. The control subsystem is adapted to control switching of the control switching device to regulate a voltage across the input port, based at least in part on a signal representing current flowing out of the output port, to maximize a signal representing power out of the output port.

In an embodiment, a method for operating a maximum power point tracking controller including an input port for electrically coupling to an electric power source and an output port for electrically coupling to a load includes the following steps: (a) repeatedly switching a control switching device of the maximum power point tracking controller between its conductive and non-conductive states to transfer power from the input port to the output port, and (b) controlling switching of the control switching device, based at least in part on a signal representing current flowing out of the output port, to regulate a magnitude of a voltage across the input port such that a signal representing power out of the output port is maximized.

In an embodiment, a method for transferring electric power between an electric power source and a load using a maximum power point tracking controller includes controlling switching of a control switching device of the maximum power point tracking controller, based at least in part on a signal representing current flowing through energy storage inductance of the maximum power point tracking controller, to regulate a voltage across the electric power source, such that: (a) the voltage across the electric power source is greater than or equal to a voltage across the load, and (b) a signal representing power transferred to the load is maximized.

In an embodiment, a multiplier includes a first and a second input port, an output port, a first field effect transistor, a

second field effect transistor, a third field effect transistor, and control circuitry. The first field effect transistor is electrically coupled in series with the first input port, the second field effect transistor is electrically coupled in series with the second input port, and the third field effect transistor is electrically coupled in series with the output port. The control circuitry is adapted to control each of the first, second, and third field effect transistors such that a magnitude of current flowing into the output port is proportional to a product of (a) a magnitude of current flowing into the first input port, and (b) a magnitude of current flowing into the second input port.

In an embodiment, an electronic filter includes an integrator subsystem and transconductance circuitry. The integrator subsystem is adapted to operate in a bipolar domain to filter an alternating current component of an input signal. The transconductance circuitry adapted to operate in a unipolar domain to generate an output current signal proportional to an average value of the input current signal.

In an embodiment, a method for filtering an input signal includes filtering an alternating current component of the input signal in a bipolar domain and generating a direct current component of the input signal in a unipolar domain.

In an embodiment, a signal scaling system includes a transconductance subsystem and control logic. The transconductance subsystem is adapted to convert an input voltage signal to an output current signal, and the transconductance subsystem includes a programmable resistor adapted to set a gain of the transconductance subsystem. The control logic is adapted to set a resistance of the programmable resistor to adjust the gain of the transconductance subsystem such that a magnitude of the output current signal is at least as large as a first threshold value.

In an embodiment, a signal level shifter for shifting complementary input voltage signals in a first power supply domain to complementary output voltage signals in a second power supply domain includes a transconductance stage and a load circuit. The transconductance stage is in the first power supply domain and is adapted to generate complementary current signals in response to the complementary input voltage signals. The load circuit is in the second power supply domain and is adapted to generate the complementary output voltage signals in response to the complementary current signals. The load circuit includes first and second inverter circuits adapted to generate the complementary output voltage signals in response to the complementary current signals.

In an embodiment, a system for determining a signal representing power in a maximum power point tracking (MPPT) controller includes a voltage filter subsystem, a current filter subsystem, a voltage scaling subsystem, a current scaling subsystem, and a multiplier. The voltage filter subsystem is adapted to generate a signal representing average voltage across an output port of the MPPT controller by filtering a signal representing voltage across the output port. The current filter subsystem is adapted to generate a signal representing average current flowing out of the output port by filtering a signal representing current flowing out the output port. The voltage scaling subsystem is adapted to generate a scaled signal representing average voltage across the output port by scaling the signal representing average voltage across the output port to be within a first predetermined range. The current scaling subsystem is adapted to generate a scaled signal representing average current flowing out of the output port by scaling the signal representing average current flowing out the output port to be within a second predetermined range. The multiplier adapted to determine the signal representing power from a product of the scaled signal represent-

ing average voltage across the output port and the scaled signal representing average current flowing out of the output port.

In an embodiment, a method for determining a signal representing power in a maximum power point tracking (MPPT) controller includes the steps of (a) filtering a signal representing current flowing out of an output port of the MPPT controller to obtain a signal representing average current flowing out of the output port; (b) filtering a signal representing voltage across the output port to obtain a signal representing average voltage across the output port; (c) scaling the signal representing average current flowing out of the output port to obtain a scaled signal representing average current flowing out of the output port; (d) scaling the signal representing average voltage across the output port to obtain a scaled signal representing average voltage across the output port; and (e) multiplying the scaled signal representing average current flowing out of the output port by the scaled signal representing average voltage across the output port to obtain the signal representing power.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 shows one model of a photovoltaic cell.

FIG. 2 shows a graph of voltage and power as a function of current for one photovoltaic cell.

FIG. 3 illustrates an electric power system including a MPPT controller, according to an embodiment.

FIG. 4 shows a block diagram of a control subsystem of the FIG. 3 MPPT controller.

FIG. 5 illustrates one possible operating mode of the control subsystem of the FIG. 3 MPPT controller.

FIG. 6 illustrates one example of operation of a current scaling subsystem with a minimum output value constraint, according to an embodiment.

FIG. 7 illustrates an electronic filter, according to an embodiment.

FIG. 8 illustrates a signal scaling subsystem, according to an embodiment.

FIG. 9 illustrates a multiplier, according to an embodiment.

FIG. 10 illustrates one possible implementation of logic and driver circuitry in an embodiment of the FIG. 3 MPPT controller where the control and freewheeling switching devices are implemented by N-channel field effect transistors.

FIG. 11 shows a graph of switching node voltage versus time for the FIG. 3 MPPT controller.

FIG. 12 illustrates a signal level shifter, according to an embodiment.

FIG. 13 illustrates an electric power system including multiple instances of the FIG. 3 MPPT controller, according to an embodiment.

DETAILED DESCRIPTION OF THE EMBODIMENTS

Applicants have developed new MPPT controllers that may achieve one or more advantages. For example, certain embodiments of the controllers may operate with a wide variety of loads and may also converge on a MPP relatively quickly.

FIG. 3 illustrates an electric power system 300 including an MPPT controller 302 electrically coupled between an electric power source 304 and a load 306. As discussed below, MPPT controller 302 is adapted to operate electric power source 304 at or near its MPP while transferring power from electric power source 304 to load 306.

5

MPPT controller 302 includes an input port 308 including input terminals 310, 312 and an output port 314 including output terminals 316, 318. A positive terminal 320 of electric power source 304 is electrically coupled to input terminal 310, and a negative terminal 322 of electric power source 304 is electrically coupled to input terminal 312, such that electric power source 304 is electrically coupled in series with input port 308. Terminals 310, 320 form part of a positive power node or rail (V_{ddh}), and terminals 312, 322 form part of a reference power node or rail (V_{ss}). Electric power source 304 is, for example, a photovoltaic device, such as a photovoltaic module including a plurality of interconnected photovoltaic cells, a single-junction photovoltaic cell, or a multi-junction photovoltaic cell. However, system 300 is not limited to photovoltaic applications. For example, in some alternate embodiments, electric power source 304 is one or more fuel cells or one or more batteries.

System 300 optionally includes one or more input capacitors 324 electrically coupled across input port 308. Capacitors 324 helps supply the ripple component of controller 302 input current *I_{in}*, thereby helping minimize the magnitude of ripple current flowing through electric power source 304. Low ripple current magnitude through electric power source 304, in turn, promotes efficient electric power source operation. In certain embodiments where MPPT controller 302 switches at a relatively high frequency, such as at 500 kilohertz or greater, capacitors 324 are multilayer ceramic capacitors, to promote small capacitor size and long capacitor life.

MPPT controller 302 includes a switching circuit 326 electrically coupled across input port 308. Switching circuit 326 includes a control switching device 328 electrically coupled between input terminal 310 and a switching node V_x, and a freewheeling switching device 330 electrically coupled between switching node V_x and input terminal 312. Output terminal 316 is electrically coupled to switching node V_x, and output terminal 318 is electrically coupled to input terminal 312. In this document, a switching device includes, but is not limited to, a bipolar junction transistor, a field effect transistor (e.g., an N-channel or P-channel metal oxide semiconductor field effect transistor (MOSFET) such as a laterally diffused metal oxide semiconductor transistor (LDMOS), a junction field effect transistor, a metal semiconductor field effect transistor), an insulated gate bipolar junction transistor, a thyristor, or a silicon controlled rectifier.

Load 306 is electrically coupled in series with output port 314, to form part of an output circuit 332 electrically coupling load 306 to switching circuit 326. Load 306 includes, for example, an inverter or a battery charger. One or more output capacitors 334 are electrically coupled across load 306 to absorb the ripple component of output current *I_{out}*. Capacitors 334 are optionally omitted, though, in embodiments where load 306 includes significant capacitance, such as in embodiments where load 306 is an inverter with significant input capacitance. In certain embodiments where MPPT controller 302 switches at a relatively high frequency, such as at 500 kilohertz or greater, capacitors 334 are multilayer ceramic capacitors to promote small capacitor size and long capacitor life. Output circuit 332 includes energy storage inductance 336. In some embodiments, energy storage inductance 336 includes one or more discrete inductors, as symbolically shown in FIG. 3. However, in some other embodiments, discrete energy storage inductors are omitted, and “parasitic” interconnection inductance associated with a loop forming output circuit 332 serves as energy storage inductance 336.

MPPT controller 302 further includes a control subsystem 338. Switching circuit 326, energy storage inductance 336,

6

and capacitors 334 collectively form a buck converter controlled by control subsystem 338. Control subsystem 338 is adapted to control switching of switching circuit 326 such that the buck converter transfers power from input port 308 to output port 314, thereby transferring power from electric power source 304 to load 306. Specifically, control subsystem 338 causes control switching device 328 to repeatedly switch between its conductive and non-conductive states, typically at a frequency of at least 100 kilohertz, to transfer power from input port 308 to output port 314. Switching device 328 is referred to as the “control” switching device because the ratio of input voltage V_{in} to output voltage V_{out} across load 306 is a function of switching device 328’s duty cycle.

Control subsystem 338 also controls switching of freewheeling switching device 330 such that it performs a freewheeling function, or in other words, such that freewheeling switching device 330 provides a path for output current *I_{out}* flowing between output terminals 316, 318 when control switching device 328 is in its non-conductive state. In some alternate embodiments, freewheeling switching device 330 is replaced with an alternative freewheeling device, such as a diode with its anode electrically coupled to reference node V_{ss} and its cathode electrically coupled to switching node V_x.

MPPT controller 302 further includes a current reconstructor subsystem 340 adapted to generate a signal *I_o* representing output current *I_{out}* flowing out of output port 314. In some embodiments, current reconstructor subsystem 340 employs systems and methods disclosed in one or more of U.S. Pat. Nos. 6,160,441 and 6,445,244 to Stratakos et al., each of which is incorporated herein by reference, to generate signal *I_o*. However, current reconstructor subsystem 340 can be implemented in other manners without departing from the scope hereof.

Control subsystem 338 further controls switching of control switching device 328, based partially on signal *I_o*, to regulate input voltage V_{in} across input port 308 such that a signal representing power out of output port 314 is maximized. In other words, control subsystem 338 adjusts magnitude of V_{in} such that MPPT controller 302 has an effective input impedance, as seen when looking into input port 308 from electric power source 304, that at least substantially maximizes power out of output port 314. Maximizing power out of output port 314 maximizes power to load 306 and also substantially maximizes power extracted from electric power source 304, since power out of output port 314 is equal to power into input port 308, neglecting losses in MPPT controller 302. Accordingly, the signal representing power out of output port 314 can represent either power into input port 308 or power out of output port 314, since both values are the same, neglecting losses in controller 302. It should be noted that while power into input port 308 and power out of output port 314 are essentially the same, input current *I_{in}* and output current *I_{out}* will differ, except when control switching device 328 operates at one hundred percent duty cycle.

In some embodiments, the signal representing power out of output port 314 represents actual power out of the output port or actual power into input port 308. In some other embodiments, though, the signal representing power out of output port 314 represents relative power out of the output port or relative power into input port 308. In these embodiments, actual output port or input port power is effectively maximized by maximizing relative output port or input port power.

Some or all of MPPT controller 302 is implemented in a common integrated circuit in certain embodiments, such as to promote small size, small parasitic impedance between components, and fast signal transfer time. In these embodiments, the integrated circuit is optionally copackaged with electric

7

power source **304** to promote small system size and minimal impedance between source **304** and controller **302**. However, MPPT controller **302** is not limited to an integrated circuit implementation and could instead be formed partially or completely from discrete components.

Although switching circuit **326**, energy storage inductance **336**, and capacitors **334** form a buck converter, these components could also be considered to form a boost converter with negative “output” current. In particular, since input voltage V_{in} is regulated and is greater than or equal to output voltage V_{out} , switching circuit **326**, energy storage inductance **336**, and capacitors **334** could be considered to form a boost converter with load **306** electrically coupled to the boost converter’s input and electric power source **304** electrically coupled to the boost converter’s output. Output current of the boost converter, though, is negative because input current I_{in} flows from electric power source **304** into MPPT controller **302**. Thus, switching circuit **326**, energy storage inductance **336**, and capacitors **334** can be considered to form either a buck converter with a regulated input voltage V_{in} , or a boost converter with a negative “output” current I_{in} , depending on one’s viewpoint.

FIG. 4 shows a block diagram of control subsystem **338**. Control subsystem **338** includes a current filter subsystem **402** adapted to filter the ripple component from signal I_o and generate a signal I_{o_avg} representing average current flowing out of output port **314**. A current scaling subsystem **404** scales I_{o_avg} to generate a signal scaled_ I_{o_avg} , which is signal I_{o_avg} scaled to be within a first range of values. A voltage filter subsystem **406** filters output port voltage V_p , which is a waveform having roughly a square wave shape, to generate a signal V_{p_avg} representing the average value of voltage V_p across output port **314**. In some alternate embodiments, however, voltage V_p is sampled across load **306**, instead of across output port **314**, thereby enabling voltage filter subsystem **406** to be omitted. A voltage scaling subsystem **408** scales V_{p_avg} to generate scaled_ V_{p_avg} , which is signal V_{p_avg} scaled to be within a second range of values. The second range of values of scaling subsystem **408** and the first range of values of scaling system **404** are typically the same to facilitate multiplying scaled_ I_{o_avg} and scaled_ V_{p_avg} . Some possible examples of filter subsystems and scaling subsystems are discussed below with respect to FIGS. 7 and 8.

Control subsystem **338** further includes a multiplier **410** adapted to multiply scaled_ I_{o_avg} and scaled_ V_{p_avg} to generate a signal P_o , which represents and is at least substantially proportional to, both of power out of output port **314** and power into input port **308**. An example of one possible implementation of multiplier **410** is discussed below with respect to FIG. 9. MPPT control circuitry **412** generates a signal V_{ref} Command, and a reference voltage generator **414** generates a reference voltage V_{ref} in response to signal V_{ref} Command. MPPT control circuit **412** and reference voltage generator **414** cooperate to set a magnitude of V_{ref} to maximize signal P_o , thereby effectively maximizing power out of output port **314** and power into input port **308**. One example of this MPPT functionality is discussed below with respect to FIG. 5.

An error amplifier **416** generates an error voltage V_{err} which is compared to a ramp signal V_{ramp} by a PWM comparator **418** to generate a PWM control signal PWM. Logic and driver circuitry **420** generates signals **422**, **424** controlling switching of switching devices **328**, **330**, respectively, from signal PWM.

Error voltage V_{err} , generated by error amplifier **416**, is given by:

$$V_{err} = -K_v * (V_{in} - V_{ref}) + K_i * I_o$$

EQN. 2

8

where K_v and K_i are scaling factors. These scaling factors are chosen such that the quantity $K_v * V_{in}$ is greater than the quantity $K_i * I_o$ under expected operating conditions to maintain stability. Additionally, scaling factor K_v is typically large because system bandwidth is roughly proportional to $K_v * I / C_{in}$, where C_{in} is total capacitance value of input capacitors **324**, and I is the average value of output current I_{out} . In some embodiments, scaling factor K_v is chosen to be inversely proportional to the expected magnitude of V_{in} , and K_i is chosen to be inversely proportional to the expected average value of output current I_{out} . Scaling factors K_v and K_i may be constants, or one or both of these factors may be dynamically adjusted, such as due to operating condition changes.

In some alternate embodiments, though, error amplifier **416** has a slightly different transfer function, given by:

$$V_{err} = -K_v * (V_{in} - V_{ref}) + K_i * I_{out_avg}$$

EQN. 3

where I_{out_avg} is an average value of current I_{out} . In certain of these embodiments, I_{out_avg} is signal I_{o_avg} from current filter subsystem **402**. In others of these embodiments, however, I_{out_avg} is derived from other filter circuitry, such as circuitry similar to current filter subsystem **402**.

The fact that V_{err} is a function of V_{in} promotes fast system response, thereby helping to quickly establish MPP operation. Additionally, the fact V_{err} is a function of signal I_o helps damp the system, thereby helping to minimize, or even eliminate, ringing during operating point step changes associated with MPPT. Furthermore, the fact that MPPT is based on output/input power, as opposed to just voltage or current, potentially enables MPPT controller **302** to work with a wide variety of loads, including both current source loads and voltage source loads.

Control subsystem **338** could be adapted such that signals processed therein are voltage signals, current signals, or a mixture of voltage and current signals, depending on the implementation of the various subsystem blocks. For example, signal I_o , representing current flowing out of output port **314**, could be either a current signal or a voltage signal, depending on the implementation of current reconstructor subsystem **340**. As another example, signal P_o , representing power out of output port **314**, could be either a current or a voltage signal, depending on the configuration of multiplier **410**. Furthermore, control subsystem **338** could be adapted such that the signals processed therein are analog signals and/or digital signals.

FIG. 5 shows one method **500** for maximizing power transferred out of output port **314** using control subsystem **338**. Method **500** can be considered a “perturb and observe” method, where V_{ref} is periodically perturbed, and the effect of the perturbation is observed to determine what direction V_{ref} magnitude should be adjusted to increase signal P_o .

In step **502**, scaling subsystems **404**, **408** are adjusted such that signals scaled_ I_{o_avg} and scaled_ V_{p_avg} are within their first and second range of values, respectively. Such signal scaling helps maximize the dynamic range of multiplier **410** when generating signal P_o . In step **504**, MPPT control circuitry **412** samples and stores multiplier output signal P_o to serve as a reference point before V_{ref} perturbation. In step **506**, MPPT control circuitry **412** changes the magnitude of V_{ref} by a first step size by changing signal V_{ref} Command to perturb V_{ref} . This V_{ref} perturbation is either positive or negative, depending on whether the last V_{ref} perturbation resulted in an increase or decrease in P_o . Specifically, if the last V_{ref} perturbation resulted in an increase in P_o , V_{ref} is stepped in the same direction. On the other hand, in the last V_{ref} perturbation resulted in a decrease in P_o , V_{ref} is stepped in the opposite direction. In step **508**, control cir-

circuitry 412 again samples P_o and determines whether the V_{ref} perturbation of step 506 increased or decreased P_o . Method 500 repeats from time to time, thereby causing control subsystem 338 to operate electric power source 304 at near or at its MPP.

It should be appreciated, though, that control subsystem 338 could be operated by methods other than method 500. For example, MPPT control circuitry 412 could alternately be adapted to determine MPP operating conditions by periodically adjusting signal V_{ref} Command to sweep V_{ref} through a range of values, calculating signal P_o at each of these values, and determining which value of V_{ref} resulted in a largest value of signal P_o .

Some embodiments of MPPT controller 302 are operable to support one hundred percent duty cycle operation of control switching device 328. In these embodiments, the perturb and observe method of FIG. 5 is modified such that the magnitude of V_{ref} is always decreased step 506 when control switching device 328's duty cycle is one hundred percent. This modification to method 500 is necessary because an increase in V_{ref} at one hundred duty cycle operation would not cause MPPT controller 302's operating conditions to change, since duty cycle increases with increasing V_{ref} , and duty cycle cannot increase beyond one hundred percent.

In some situations, the magnitude of signal I_o may be too small for scaling within the first range of values, even at a maximum gain setting of current scaling subsystem 404. A small value of scaled_ I_o _avg, in turn, may make it difficult or impossible to determine signal P_o from the product of scaled_ I_o _avg and scaled_ V_p _avg. Accordingly, current scaling subsystem 404 is optionally adapted such that the magnitude of scaled_ I_o _avg does not fall below a minimum threshold value, no matter how small the magnitude of I_o _avg. In these embodiments, signal scaled_ I_o _avg will not change in response to a V_{ref} perturbation at small output current I_{out} values, and average voltage across output port 314, and not output power, is therefore maximized under these conditions. This technique of handling MPP operation at small I_{out} values advantageously does not require that MPPT control circuitry 412 change modes to support low I_{out} levels or introduce a discontinuity in the I_{out} transfer function.

FIG. 6 illustrates one example of operation of an embodiment where signal scaled_ I_o _avg is not permitted to fall below a threshold value. In this embodiment, current scaling system 404 is adapted to maintain signal scaled_ I_o _avg within a first range of values bounded by upper and lower thresholds 602, 604, no matter how small the magnitude of signal I_o _avg. During input range 606, magnitude of signal I_o _avg is so small that current scaling subsystem system 404 sets signal scaled_ I_o _avg to its minimum threshold value corresponding to lower threshold 604. Dashed line 608 represents what magnitude scaled_ I_o _avg would have if current scaling subsystem 404 did not constrain the minimum value of scaled_ I_o _avg to lower threshold 604.

In some other embodiments, current scaling subsystem 404 is adapted to add a positive offset value to scaled_ I_o _avg at small magnitude of I_o _avg, such that scaled_ I_o _avg does not fall below a minimum threshold value. For example, consider again input range 606 of FIG. 6. In alternate certain embodiments, current scaling subsystem 404 is adapted to add a positive offset value to scaled_ I_o _avg when I_o _avg is within input range of values 606, such that scaled_ I_o _avg does not fall below lower threshold 604. In these embodiments, scaled_ I_o _avg retains the same shape as I_o _avg. Thus, dashed line portion 608 would remain a diagonal line, but portion 608 would be shifted into the range of values bounded by upper and lower thresholds 602, 604.

Control subsystem 338 optionally further includes additional V_{ref} control circuitry 426 to implement one or more additional features of controller 302. Although additional V_{ref} control circuitry 426 is symbolically shown as a discrete block, it is optionally integrated into one or more of the other blocks of control subsystem 338, such as into MPPT control circuitry 412.

Additional V_{ref} control circuitry 426 is optionally adapted to prevent V_{in} from falling below a minimum value and/or from rising above a maximum value. It may be desirable to limit the minimum V_{in} value to support proper operation of MPPT controller 302. On the other hand, it may be desirable to limit the maximum value of V_{in} to prevent damage to electric power source 304 and/or MPPT controller 302 due to a high voltage condition, and/or to promote safety. Accordingly, in some embodiments, additional V_{ref} control circuitry 426 is adapted to override MPPT control circuitry 412 and prevent V_{ref} from further decreasing, or even increase V_{ref} , if V_{in} falls below a threshold value, or if decreasing V_{ref} would cause V_{in} to fall below the threshold value. Similarly, in some embodiments, additional V_{ref} control circuitry 426 is adapted to override MPPT control circuitry 412 and prevent a further increase in V_{ref} if V_{in} rises above a threshold value, or if increasing V_{in} would cause V_{ref} to rise above the threshold value.

Furthermore, in some embodiments, additional V_{ref} control circuitry 426 is adapted to override MPPT control circuitry 412 and decrease V_{ref} if a magnitude of signal I_o falls below a threshold value, thereby preventing possible unreliable operation associated with very small output current I_{out} magnitude. The threshold value is set just above a minimum output current I_{out} magnitude resolvable by current reconstructor subsystem 340, in a particular embodiment. For example, consider an embodiment where current scaling subsystem 404 is adapted such that the magnitude of scaled_ I_o _avg does not fall below a minimum threshold value. In this embodiment, average voltage across output port 314, and not output power, is maximized when signal I_o falls below the threshold value, as discussed above. Such maximization of average output port 314 voltage, though, may not maximize electric power source 304 power; instead electric power source 304 may operate at a high voltage, low current point below its MPP. Decreasing V_{ref} , however, will increase control switching device 328's duty cycle, thereby increasing output current I_{out} magnitude and causing electric power source 304 to operate closer to its maximum power point. Decreasing V_{ref} may also potentially increase output current I_{out} magnitude such that normal MPPT can resume. Accordingly, some embodiments incorporate both (1) circuitry to prevent magnitude of scaled_ I_o _avg from falling below a threshold value, and (2) circuitry to decrease V_{ref} if magnitude of signal I_o falls below a threshold value.

In certain embodiments, control subsystem 338 is adapted to operate control switching device 328 at a fixed duty cycle if signal I_o drops below a threshold value indicating potential negative output current. Operating switching device 328 at a fixed duty cycle facilitates operating with reverse current, where I_{out} has a negative value, instead of a positive value. Reverse current conditions may occur in applications where one or more additional electric power sources are electrically coupled to output port 314, such as in applications including strings of parallel connected photovoltaic devices. It is anticipated that control subsystem 338 will operate control switching device 328 at a large fixed duty cycle, such as ninety five or one hundred percent duty cycle, when signal I_o indicates potential negative output current. The threshold value indicating potential negative output current will typically be set

11

lower than other low output current thresholds, such as the threshold to decrease Vref if Io falls below a threshold value, discussed above.

In some situations, it may be desirable to reduce the size of Vref perturbations at high control switching device 328 duty cycle to promote more robust MPPT, since large Vref step sizes at high duty cycle may cause undesirable operation. As can be seen from EQN. 2 and FIG. 4, duty cycle change in response to a given Vref step is not necessarily constant because duty cycle change may vary as a function of Io and other factors. Duty cycle change is typically greater at small Io values than at large Io values, and low Io values typically correspond to large duty cycle operation. Thus, a given Vref step will often cause a relatively large duty cycle step at high duty cycle operation. A large duty cycle step, in turn, may negatively affect MPPT and/or load 306 operation.

Accordingly, in some embodiments, additional Vref control circuitry 426 cooperates with MPPT control circuitry 412 such that MPPT control circuitry 412 changes Vref by a smaller step size at high duty cycle than at low duty cycle. In particular, circuitry 412, 426 causes Vref to be changed by a first step size during MPPT when a command to control a duty cycle of control switching device 328 is below a first threshold value, and circuitry 412, 426 causes Vref to be changed by a second step size during MPPT when a command to control a duty cycle of control switching device 328 is above a second threshold value. The second step size is smaller than the first step size, and the first threshold value is less than or equal to the second threshold value. It is envisioned that in many embodiments the first threshold value will be less than the second threshold value to achieve hysteresis between large and small Vref step size operating modes. The command to control duty cycle of control switching device 328 is derived, for example, from signal 422 generated by logic and driver circuitry 420.

It may also be desirable to reduce the size of Vref perturbations when operating at or near MPP, since Vref perturbations will temporarily cause electric power source 304 to operate away from its MPP in such case. Thus, in some embodiments, additional Vref control circuitry 426 cooperates with MPPT control circuitry 412 such that MPPT control circuitry 412 changes Vref by a smaller step size when electric power source 304 is close to its MPP, than when electric power source 304 is far from its MPP. In particular, circuitry 412, 426 causes Vref to be changed by a first step size during MPPT when a difference in Po between successive Vref perturbations is below a first threshold value, and circuitry 412, 426 causes Vref to be changed by a second step size during MPPT when a difference in Po between successive Vref perturbations is above a second threshold value. The second step size is larger than the first step size, and the first threshold value is less than or equal to the second threshold value. It is envisioned that in many embodiments the first threshold value will be less than the second threshold value to achieve hysteresis between large and small Vref step size operating modes.

It is desirable to quickly reach MPP operation in many applications. Therefore, in certain embodiments, control subsystem 338 is adapted to quickly change Vref when MPPT controller 302 is operating at extreme points that are not likely to represent MPP operation, such as at start-up, thereby facilitating quick convergence on MPP operation. In these embodiments, MPPT control circuitry 412 and additional Vref control circuitry 426 cooperate such that MPPT control circuitry 412 changes Vref at a faster rate when control switching device 328 is at extreme duty cycle conditions, than when control switching device 328 is at normal duty cycle condi-

12

tions. In particular, circuitry 412 changes Vref at a first rate when a command to control duty cycle of control switching device 328 is within a first range of values, and circuitry 412 changes Vref at a second rate when a command to control duty cycle of control switching device 328 is within a second range of values. The second rate is greater than the first rate, and the second range of values represents extremely large or small duty cycle command, while the first range of values represents normal duty cycle command. For example, in one embodiment, the first range of values represents a command that control switching device 328's duty cycle be between zero and one hundred percent, while the second range of values represents a command that control switching device 328's duty cycle be less than zero or greater than 100 percent.

In embodiments where electric power source 304 is a photovoltaic device, it may be possible to roughly estimate the device's MPP from its open circuit voltage before MPPT controller 302 begins switching. In particular, a photovoltaic device's MPP typically occurs somewhere between eighty percent to ninety-five percent of its open circuit voltage. Initially setting Vref to this range of photovoltaic device open circuit voltage may speed MPP operation.

Therefore, in some embodiments, additional Vref control circuitry 426 is adapted to set an initial value of Vref based at least partially on an initial average voltage across input port 308, at start-up of MPPT controller 302. For example, in some embodiments, additional Vref control circuitry 426 is adapted to set an initial value of Vref at start-up so that control switching device 328 initially operates at a duty cycle that roughly maintains the average voltage across input port 308 to a fraction of its initial value, such as to within eighty to ninety-five percent of its initial value. MPPT control circuitry then adjusts Vref magnitude to achieve MPP operation, such as discussed above with respect to FIG. 5.

In certain embodiments, control switching device 328 and/or freewheeling switching device 330 include one or more switching devices that are dynamically sized field effect transistors (FETs). Such dynamically sized FETs each include a number of individually controllable elements in the form of constituent FETs electrically coupled in parallel, where the number of such constituent FETs that are active can be varied to dynamically size the FET. The FET's properties can be varied by changing its size, i.e., the number of its constituent FETs that are active. For example, overall FET channel resistance can be decreased by increasing FET size, i.e., increasing the number of constituent FETs that are active. However, the more constituent FETs that are active, the greater the gate capacitance and associated switching loss (assuming each constituent FET is driven by a common driver). For each duty cycle, there is typically an optimal FET size that minimizes the sum of resistance-related and gate-capacitance-related losses.

In some embodiments including one or more dynamically sized FETs and current reconstructor subsystem 340, control subsystem 338 decreases FET size, i.e., decreases the number of active constituent FETs, if the magnitude of signal Io_avg falls below a threshold value, to change the gain of current reconstructor subsystem 340. In these embodiments, gain of current reconstructor subsystem 340 is at least partially dependent on the number of constituent FETs that are active, and gain increases as the number of active constituent FETs decreases. Thus, decreasing FET size increases reconstructor gain and magnitude of signal Io_avg, thereby potentially reducing, or even eliminating, difficulties associated with low magnitude of signals Io_avg/Io_avg_scaled, such as the difficulties discussed above with respect to FIG. 6. Accordingly, decreasing FET size may enable control subsystem 338 to

13

perform MPPT at lower output current I_o magnitudes than would be feasible without decreasing FET size.

FIG. 7 illustrates an electronic filter 700. Each of current and voltage filter subsystems 402, 406 include, for example, an instance of filter 700. However, filter subsystems 402 and/or 406 could alternately be implemented with different filter types. For example, in some other embodiments, voltage filter subsystem 406 is implemented with an R-C filter to promote simplicity and low cost. Furthermore, electronic filter 700 is not limited to use in control subsystem 338.

Filter 700 is operable to generate an output current signal 702 representing an average value of an input current signal 704. Output current signal 702 is a unipolar signal under intended operating conditions, even in situations where input current signal 704 is a bipolar signal, such as when input current signal 704 has a small direct current (DC) component and a large alternating current (AC) component. In the context of this document, a unipolar signal remains either positive or negative. In other words, a unipolar signal does not change between positive and negative values. A bipolar signal, on the other hand, changes between positive and negative values. As known in the art, it is often much simpler to process a unipolar signal than a bipolar signal. For example, a two-transistor current mirror can be used to scale a unipolar signal, while significantly more complicated circuitry is required to scale a bipolar signal. Accordingly, the fact that output current signal 702 is a unipolar under intended operating conditions may be particularly advantageous in certain applications.

Filter 700 includes an integrator subsystem 706 and transconductance circuitry including first and second transconductance amplifiers 708, 710. Integrator subsystem 706 includes an integrator 712 having inverting and non-inverting input terminals, a resistive device 714 electrically coupled across the integrator's input terminals, and a constant voltage source 716 electrically coupled between the integrator's non-inverting input and a reference node 718. The integrator's inverting input is electrically coupled to a node 724. An AC component 720 of input current signal 704 flows through resistive device 714 into node 724, thereby creating an AC signal across the integrator 712's input terminals. Integrator 712 integrates this AC signal and generates an integrator signal AVG representing the average value of input current signal 704.

Second transconductance amplifier 710 generates a current signal 722 flowing into node 724 in response to integrator signal AVG, such that integration subsystem 706 and second transconductance amplifier 710 collectively form a closed-loop low pass filter. Current signal 722 represents the DC component of input current signal 704, such that DC current signal 722 and AC current signal 720 collectively form input current signal 704 flowing out of node 724. First transconductance amplifier 708 is also controlled by integrator signal AVG to generate output current signal 702 which mirrors DC current signal 722 and is therefore proportional to the average value of input current signal 704.

Accordingly, integrator subsystem 706 operates in a bipolar domain to filter the bipolar or AC component of input current signal 704, while first and second transconductance amplifiers 708, 710 operate in a unipolar domain to handle the unipolar or DC component of input current signal 704. This separate handling of the bipolar and unipolar components of input current signal 704 promotes ease of filtering the bipolar AC component of input current signal 704 while maintaining accuracy of the unipolar DC component.

FIG. 8 illustrates a signal scaling subsystem 800. Each of current and voltage scaling subsystems 404, 408 include, for example, an instance of scaling subsystem 800. However,

14

scaling subsystems 404 and/or 408 could alternately include different scaling circuitry. Furthermore, signal scaling subsystem 800 is not limited to use in control subsystem 338.

Subsystem 800 includes an amplifier 802, a control transistor 804, a programmable resistor 806, and mirror transistors 808, 810. In the context of this document, field effect transistor terminals labeled G, D, and S correspond to gate, drain, and source terminals, respectively. An output 812 of amplifier 802 drives control transistor 804, which is electrically coupled between mirror transistor 808 and programmable resistor 806. Mirror transistor 808 is electrically coupled between a high side power node or rail 814 and control transistor 804, and programmable resistor 806 is electrically coupled between control transistor 804 and a reference node or rail 816. An inverting input of amplifier 802 is electrically coupled to a node 818 joining control transistor 804 and programmable resistor 806, and a non-inverting input of amplifier 802 receives an input voltage signal 820.

Amplifier 802 controls operation of control transistor 804 such that a current signal 822 flowing through transistor 804 and programmable resistor 806 causes a voltage across programmable resistor 806 to equal input voltage signal 820. Thus, amplifier 802 regulates voltage across variable resistor 806 in response to input voltage signal 820. Transistor 810 mirrors current signal 822 to generate an output current signal 824 proportional to current signal 822. A resistance value of programmable resistor 806 is set by control logic 826. Thus, amplifier 802, control transistor 804, programmable resistor 806, and mirror transistors 808, 810 form a transconductance subsystem operable to convert input voltage signal 820 to output current signal 824, where control logic 826 sets resistance of programmable resistor 806 to control transconductance subsystem gain.

As gain range is increased, the number of gain steps required to achieve a desired gain change at each step also increases. Thus, in certain embodiments, programmable resistor 806 and control logic 826 are chosen such that gain changes by a factor of square root of two at each gain step, to provide a compromise between a large gain range and number of gain steps.

Subsystem 800 further includes an additional mirror transistor 826 which mirrors current signal 822. A comparator 828 compares the mirrored current signal to a reference current signal 830, and comparator 828 outputs a GainOK signal if the mirrored current signal is at least as large as the reference current signal. Upon assertion of an enable signal ENABLE, control logic 826 sets programmable resistor 806 to its largest resistance value, thereby setting gain to a minimum value. Control logic 826 then incrementally decreases resistance of programmable resistor 806 in response to a clock signal CLK, thereby incrementing gain, until assertion of a GainOK signal from comparator 828. Thus, signal scaling subsystem 800 scales output current signal 824 to have a magnitude at least as large as reference signal 830, upon assertion of signal ENABLE. In embodiments of control subsystem 338 incorporating instances of subsystem 800 as scaling subsystems, signal ENABLE is asserted, for example, upon execution of step 502 of method 500 (FIG. 5).

In certain embodiments of control subsystem 338 incorporating instances of subsystem 800 as scaling subsystems, a V_{ref} perturbation might cause a large increase in scaled I_o average and/or scaled V_p avg, before scaling subsystems 404, 408 rescale their outputs. Such large increase in signal magnitude may saturate multiplier 410, thereby causing inaccurate MPPT operation. Accordingly, subsystem 800 optionally further includes mirror transistor 832, comparator 834, and reference current source 836 to detect a large

15

increase in output current signal **824** magnitude, which may cause improper MPPT operation.

In particular, mirror transistor **832** mirrors current signal **822**, and comparator **834** compares the mirrored current signal to a reference current signal **836**, which is larger than reference current signal **830**. In some embodiments, reference current signal **836** is four times reference current signal **830** and represents a threshold value at which output current signal **824** magnitude is considered excessively large. Comparator **834** outputs a GainHi signal if the magnitude of the mirror current is at least as large as reference current signal **836** magnitude.

In certain embodiments of control subsystem **338** incorporating instances of subsystem **800** as scaling subsystems, MPPT control circuitry **412** responds to a GainHi assertion by assuming that the perturbation increases Po magnitude, without comparing Po magnitudes before and after the perturbations. As discussed above, a Po calculation may not be accurate after large signal increase as indicated by a GainHi assertion, and comparing Po values after a GainHi assertion may cause erroneous MPPT operation.

Certain embodiments of signal scaling subsystem **800** may achieve one or more advantages that would not necessarily be realized by conventional signal scaling subsystems. For example, gain of subsystem **800** is inversely proportional to resistance of programmable resistor **806**, thereby allowing subsystem **800** to achieve a wide range of gain, simply by changing resistance of programmable resistor **806**.

As another example, the configuration of subsystem **800** promotes quick settling of gain after a gain step change, with a settling time that remains relatively constant as gain changes. In particular, control transistor **804** acts as a near unity gain buffer, regardless of the resistance of programmable resistor **806**, neglecting second order effects. Thus, the loop gain of amplifier **802** is nearly constant as resistor **806** changes, resulting in the bandwidth and settling time of amplifier **802** also remaining relatively independent of resistor **806** resistance value. Accordingly, amplifier **802** can typically be selected to provide sufficiently fast settling time without having to account for gain changes.

FIG. 9 illustrates a multiplier **900**. Multiplier **410** of control subsystem **338** is implemented, for example, using multiplier **900**. However, multiplier **410** could alternately be implemented in a different manner. Furthermore, multiplier **900** is not limited to use in control subsystem **338**.

Multiplier **900** includes a first input port **902**, a second input port **906**, and an output port **910**. A first input current signal **904** flows into first input port **902**, a second input current signal **908** flows into second input port **906**, and an output current signal **912** flows into output port **910**. A first field effect transistor **914** is electrically coupled in series with first input port **902**, a second field effect transistor **916** is electrically coupled in series with second input port **906**, and a third field effect transistor **918** is electrically coupled in series with output port **910**. As discussed below, multiplier **900** further includes control circuitry adapted to control each of the first, second, and third transistors such that the transistors operate in their linear or triode regions and the magnitude of output current signal **912** is proportional to the product of (a) the magnitude of first input current signal **904**, and (b) the magnitude of second input current signal **908**.

The control circuitry includes fourth, fifth, and sixth field effect transistors **920**, **922**, **924**, as well as amplifiers **926**, **928**. The gates of first and third transistors **914**, **918** are electrically coupled together at a common node **932**, while the gates of second, fourth, and fifth transistors **916**, **920**, **922** are electrically coupled together at a different common node **940**.

16

Fourth and fifth transistors **920**, **922** each have x matched unit cell transistors, where x is an integer greater than zero. Accordingly, transistors **920**, **922** will have the same channel resistance when operated at the same gate-to-source voltage, since both transistors have the same number of matched unit cell transistors. First, second, and third transistors **914**, **916**, **918**, on the other hand, have m*x matching unit cell transistors, where m is an integer greater than one. Accordingly, each of transistors **914**, **916**, and **918** will have a channel resistance equal to R/m, where R is the channel resistance of transistor **920** or **922**, assuming that each of transistors **914**, **916**, **918**, **920**, and **922** are operated at a common gate-to-source voltage.

Amplifier **926** is adapted to control the gate of first transistor **914** such that its channel resistance, R_{914} , is determined by the voltage at reference node **938** and first input current signal **904**. Specifically, amplifier **926** forces the voltage across first transistor **914**, which is equal to the voltage on node **934**, to be the same as the voltage across fourth transistor **920**, such that:

$$R_{914} = V_{938} / I_{904} \quad \text{EQN. 4}$$

where V_{938} is the voltage on node **938** and I_{904} is the magnitude of first input current signal **904**. Each transistor **914**, **918** has the same channel resistance since both transistors have m*x matching unit cell transistors and are driven by a common gate-to-source voltage from amplifier **926**.

Amplifier **928** controls the gate of sixth transistor **924** such that the voltage across second transistor **916** is the same as the voltage across third transistor **918**, which is equal to voltage on node **930**. Accordingly, the magnitude of output current signal **912** is given by:

$$I_{912} = V_{942} / R_{914} = V_{942} / (V_{938} / I_{904}) = I_{904} * (V_{942} / V_{938}) \quad \text{EQN. 5}$$

where I_{912} is the magnitude of output current signal **912** and V_{942} is the voltage on node **942**. Voltage at reference node **938** is given by the following:

$$V_{938} = (I_{ref} / m) * R_{920} \quad \text{EQN. 6}$$

where R_{920} is the channel resistance of fourth transistor **920**. Fourth and fifth transistors **920**, **922** form a current mirror configured such that a drain-to-source current flowing through fifth transistor **922** has a magnitude equal to I_{ref} , and a drain-to-source current flowing through fourth transistor **920** has a magnitude equal to I_{ref} / m . As discussed below, this configuration helps ensure that transistors **914**, **916**, **918**, **920** operate in their triode region, as required for proper operation.

The gates of second and fourth transistors **916**, **920** are both coupled to node **940**, such that channel resistance R_{916} of second transistor **916** is given by:

$$R_{916} = R_{920} / m \quad \text{EQN. 7}$$

Accordingly, it can be shown that the voltage on node **942** is given by:

$$V_{942} = I_{908} * R_{916} = I_{908} * (R_{920} / m) \quad \text{EQN. 8}$$

where I_{908} is the magnitude of second input current signal **908**. The ratio of voltage at node **942** to the ratio of voltage at node **938** is therefore given by:

$$V_{942} / V_{938} = I_{908} * (R_{920} / m) / [(I_{ref} / m) * R_{920}] = I_{908} / I_{ref} \quad \text{EQN. 9}$$

Substituting EQN. 9 into EQN. 5 yields the following:

$$I_{912} = (I_{904} * I_{908}) / I_{ref} \quad \text{EQN. 10}$$

EQN. 10 shows that the magnitude of output current signal **912** is proportional to the product of (a) magnitude of first

input current signal **904** and (b) magnitude of second input current signal **908**. EQN. 10 also shows that output current signal **912** is inversely proportional to reference current signal I_{ref} .

Multiplier **900** may achieve one or more advantages that would not necessarily be realized by conventional multipliers. For example, input signals **904**, **908** and output signal **912** are each current signals, as opposed to voltage signals, which may ease interfacing multiplier **900** with external circuitry in certain applications. As another example, certain embodiments will operate with a single unipolar power supply and signals referenced to ground, as opposed to requiring a split power supply or that signals be referenced to a mid-rail potential. Additionally, certain embodiments of multiplier **900** do not require resistors, as shown in FIG. 9. Forming a circuit without resistors may be particularly advantageous in integrated circuit implementations, since resistors can occupy significant integrated circuit die area.

Furthermore, the configuration of multiplier **900** promotes reliable operation at less than optimal conditions, such as at temperature and/or manufacturing process corners, by helping ensure that transistors **914**, **916**, **918**, **920** operate in their linear or triode regions, as required for proper operation. In particular, configuring multiplier **900** such that a drain-to-source current of fourth transistor **920** is m times smaller than a drain-to-source current of fifth transistor **922** ensures that fourth transistor **920** operates in its triode region, and that voltage on reference node **938** is relatively low. The low voltage on reference node **938** also causes first and third transistors **914**, **198** to operate in their triode regions, since amplifier **926** forces the voltage across first transistor **914** to be the same as the voltage on reference node **938**. Second transistor **916**, in turn, will operate in its triode region as long as its drain-to-source current is less than $m \cdot I_{ref}$, since this transistor is controlled by fifth transistor **922**. Thus, the larger value of parameter m , the further transistors **914**, **916**, **918**, **920** operate in their triode region. As long as m is greater than two and the magnitude of both first and second input current signals **904**, **908** is less than I_{ref} , transistors **914**, **916**, **918**, **920** will operate in their triode regions, even at temperature and/or manufacturing process corners.

As discussed above, logic and driver circuitry **420** (FIG. 4) outputs two signals **422**, **424**, controlling switching devices **328**, **330**. Each of signals **422**, **424** will typically be in a different power supply domain due to the control and freewheeling switching devices being referenced to difference nodes.

For example, FIG. 10 one possible implementation of logic and driver circuitry **420** in an embodiment where control switching device **328** is implemented as an N-channel field effect transistor **1028**, and freewheeling switching device **330** is implemented as an N-channel field effect transistor **1030**. It should be understood, though, that MPPT controller **302** is not limited to the FIG. 10 implementation.

A regulator **1002** generates a "housekeeping" power rail (V_{cc}) from positive power node V_{ddh} . V_{cc} is referenced to reference power node V_{ss} , and V_{cc} , or another rail derived therefrom, is used to power much of the circuitry, such as PWM comparator **418**, in control subsystem **338**.

Signal PWM is in the V_{cc}/V_{ss} power supply domain, due to PWM comparator **418** being powered from the V_{cc} power rail, which is referenced to V_{ss} . Control logic **1004** of circuitry **420** converts signal PWM into a control switch signal **1006** for controlling transistor **1028** and into a freewheeling signal **1008** for controlling transistor **1030**. Both of signals **1006**, **1008** are in the V_{cc}/V_{ss} power supply domain. Driver circuitry **1010** generates a gate drive voltage signal V_{gs1} in

response to freewheeling signal **1008**. Gate drive voltage signal V_{gs1} drives transistor **1030**, or in other words, controls the gate to source voltage of transistor **1030** to control switching of transistor **1030**. Transistor **1030**'s source is electrically coupled to reference node V_{ss} . Accordingly, gate drive voltage signal V_{gs1} is also in the V_{cc}/V_{ss} power supply domain.

Control transistor **1028** is referenced to switching node V_x , instead of to reference node V_{ss} . A bootstrap component of driver and bootstrap circuitry **1012** generates a "bootstrap" voltage rail (V_{bst}), which is referenced to switching node V_x , to allow circuitry **1012** to drive transistor **1028**'s gate positive with respect to the transistor's source. An energy storage element, such as a capacitor **1014**, is used to store energy for the bootstrap voltage rail. Driver and bootstrap circuitry **1012** generates a gate drive voltage signal V_{gs2} in the V_{bst}/V_x power supply domain to drive transistor **1028**.

Signals in the V_{cc}/V_{ss} domain cannot be directly electrically coupled to the V_{bst}/V_x domain due to the two domains having difference references. In particular, reference V_{ss} in the V_{cc}/V_{ss} domain is essentially at a constant voltage. The V_{bst}/V_x domain, on the other hand, is referenced to switching node V_x , which has a large voltage swing. For example, FIG. 11 shows a graph of voltage on switching node V_x versus time. Signal PWM is also shown on the graph by dashed lines. As can be observed, voltage of switching node V_x changes significantly in response to changes in signal PWM.

Accordingly, logic and driver circuitry **420** includes a level shifter **1016** to shift control switch signal **1006** from the V_{cc}/V_{ss} domain to a signal **1018** in the V_{bst}/V_x domain. Thus, level shifter **1016** interfaces control logic **1004**, which is in the V_{cc}/V_{ss} domain, with driver and bootstrap circuitry **1012**, which is in the V_{bst}/V_x domain. FIG. 12 shows a signal level shifter **1200**, which is one possible implementation of level shifter **1016**. It should be appreciated, however, that level shifter **1016** could be implemented in other manners. Additionally, level shifter **1200** is not limited to use in circuitry **420**.

Level shifter **1200** receives complementary input signals INP, INN, which are in the V_{cc}/V_{ss} power supply domain. An inverter **1202** inverts signal INP, and an inverter **1204** inverts signal INN, before these signals are coupled to a transconductance stage **1206** in the V_{cc}/V_{ss} power supply domain. Transconductance stage **1206** is adapted to generate complementary current signals **1208**, **1210** in response to input signals INP, INN.

The output of inverter **1202** is electrically coupled to the gates of P-channel and N-channel field effect transistors **1212**, **1214**, which are configured to control the voltage across the gate and source terminals of N-channel field effect transistor **1216**. The output of inverter **1204** is electrically coupled to the gates of P-channel and N-channel field effect transistors **1218**, **1220**, which are configured to control the voltage across the gate and source terminals of N-channel field effect transistor **1222**. When signal INP is in its high state, transistor **1212** is in its conductive state, and transistor **1214** is in its non-conductive state, so that the gate-to-source voltage of transistor **1216** is essentially zero, and transistor **1216** is in its non-conductive state. On the other hand, when signal INP is in its low state, transistor **1212** is in its non-conductive state, and transistor **1214** is in its conductive state, such that gate-to-source voltage of transistor **1216** is essentially equal to $V_{cc}-V_{ss}$, and transistor **1216** is in its conductive state. Transistors **1218**, **1220**, and **1222** operate in an analogous manner in response to signal INN.

Complementary current signals **1208**, **1210** are electrically coupled to a load circuit **1224** in the V_{bst}/V_x power supply

domain, which is adapted to generate complementary output voltage signals OUTP, OUTN in response to current signals **1208**, **1210**. Load circuit **1224** includes P-channel field effect transistors **1226**, **1228**. Transistor **1226** is electrically coupled between Vbst and transistor **1222** and is adapted to operate in its linear region, thereby limiting the magnitude of current signal **1208**. Similarly, transistor **1228** is electrically coupled between Vbst and transistor **1216** and is adapted to operate in its linear region, thereby limiting the magnitude of current signal **1210**.

Load circuit **1224** further includes first and second inverter circuits **1230**, **1232** referenced to the Vbst/Vx power supply domain. First inverter circuit **1230** is adapted to generate output signal OUTP from current signal **1208**, while second inverter circuit **1232** is adapted to generate signal OUTN from current signal **1210**. Inverter **1230** includes a P-channel field effect high side transistor **1234** and an N-channel field effect low side transistor **1236**. Transistor **1234** is electrically coupled between a high side rail S2 of the inverter and an output node **1238**, and transistor **1236** is electrically coupled between output node **1238** and Vx. The gates of transistors **1234**, **1236** are electrically coupled to drains of transistors **1222**, **1226**, which are connected to a high side rail S1 of inverter circuit **1232**. Similarly, inverter circuit **1232** includes a P-channel field effect high side transistor **1240** and an N-channel field effect low side transistor **1242**. Transistor **1240** is electrically coupled between the high side rail S1 of the inverter and an output node **1244**, and transistor **1242** is electrically coupled between output node **1244** and Vx. The gates of transistors **1240**, **1242** are electrically coupled to the drains of transistors **1216**, **1228**, which are connected to inverter circuit **1230** high side rail S2.

High side rail S2 of inverter circuit **1230** is electrically coupled to Vbst by a P-channel field effect transistor **1246**, and high side rail S1 of inverter circuit **1232** is electrically coupled to Vbst by a P-channel field effect transistor **1248**. Transistors **1246** and **1248** are cross-coupled, in that the gate of transistor **1246** is electrically coupled to the drain of transistor **1248**, and the gate of transistor **1248** is electrically coupled to the drain of transistor **1246**. The gate of transistor **1246** is electrically coupled to high side rail S1 of inverter circuit **1232**, and the gate of transistor **1248** is electrically coupled to the high side rail S2 of inverter circuit **1230**. Cross-connected transistors **1246**, **1248** achieve regenerative feedback, thereby promoting fast switching of high side rails S1, S2 and corresponding fast operation of level shifter **1200**.

Inverter circuits **1230** are **1232** are skewed in the sense that high side transistors **1234**, **1240** are "stronger" than low side transistors **1236**, **1242**. Specifically, high transistor **1234** is operable to pull output node **1238** up to at least fifty percent of the electrical potential on high side rail S2 when low side transistor **1236** is in its conductive state. Similarly, high side transistor **1240** is operable to pull up output node **1244** to at least fifty percent of the electrical potential on high side rail S1 when low side transistor **1242** is in its conductive state. Such skewing of inverter circuits **1230**, **1232** is required to achieve proper operation in certain situations.

For example, consider the situation where INP is asserted. Transistor **1222** will be in its conductive state, and transistor **1216** will be in its non-conductive state, such that high side rail S1 will be pulled down close to Vss and high side rail S2 will be pulled up close to Vbst. Thus, high side transistor **1234** will operate in its conductive state and low side transistor **1236** will operate in its non-conductive state, such that output signal OUTP is high. On the other hand, high side transistor **1240** will operate in its non-conductive state and low side

transistor **1242** will operate in its conductive state, such that output signal OUTN is low. However, if the electrical potential of switching node Vx drops below the electrical potential of reference power node Vss, such as due to freewheeling action of freewheeling switching device **330**, it will not be possible to turn low side transistor **1236** off, since its gate to source voltage will be positive. Thus, inverter circuit **1230** is skewed such that high side transistor **1234** can pull-up output node **1238** even when low side transistor **1236** is in its conductive state, to allow inverter circuit **1230** to change its output state from low to high when Vx is at a negative electrical potential with respect to Vss. Inverter circuit **1232** is skewed for similar reasons, i.e., to allow inverter to change its output state from low to high when Vx is at a negative electrical potential with respect to Vss.

Load circuit **1224** further includes diodes **1250**, **1252**. The anode of diode **1250** is electrically coupled to Vx, and the cathode of diode **1250** is electrically coupled to high side rail S1. The anode of diode **1252** is electrically coupled to Vx, and the cathode of diode **1252** is electrically coupled to high side rail S2. Diodes **1250**, **1252** clamp any voltage swing across transistors **1226**, **1228**, thereby helping protect these transistors from transient voltage excursions.

Transistors **1222**, **1216** also help speed switching of level shifter **1200** in certain circumstances. For example, consider again the scenario where signal INP is high and signal INN is low. As discussed above, transistors **1222**, **1234**, and **1242** will be in their conductive states, and transistors **1216**, **1236**, and **1240** will be in their non-conductive states, such that signal OUTP is high and signal OUTN is low. In some cases, Vx will be at negative electrical potential with respect to Vss, result in Vbst being at negative electrical potential with respect to Vcc. Accordingly, the drain of transistor **1216** will be at a lower electrical potential than its gate, resulting in transistor **1216** conditionally switching from its non-conductive state to its conductive state when its gate-to-drain voltage exceeds a threshold value Vth, which is typically around 0.4 volts. This conduction of transistor **1216** will cause current to flow from Vcc through transistors **1212**, **1216** to rail S2, thereby pulling-up up rail S2 above Vbst by about the difference between a diode voltage and Vth, which speeds switching of inverter circuit **1230**. High side rail S2 cannot be pulled more than about a diode voltage (approximately 0.7 volts) above Vbst due to a drain-source body diode (not shown) of transistor **1246** clamping rail S2 to Vbst. Conduction of transistor **1222** speeds up switching of inverter circuit **1232** in a similar manner when Vx is negative.

Level shifter **1200** may achieve one or more advantages that may not be realized by conventional level shifters. For example, certain embodiments of level shifter **1200** are fast, or in other words, introduce minimal propagation delay when converting complementary input signals INP, INN to complementary output signals OUTP, OUTN. For instance, in certain embodiments, the propagation delay is less than 7 nanoseconds, even in situations where the electrical potential of Vx is below that of Vss. This relative speed of level shifter **1200** is due to, in part, incorporation of cross-coupled transistors **1246**, **1248**, as well as the fact that transistors **1216**, **1222** promote fast switching when Vx is negative with respect to Vss, as discussed above. Fast operation is important, for example, to prevent simultaneous conduction of control and freewheeling switching devices **328**, **300**, sometimes referred to as "shoot through," due to delays in switching control switching device **328**.

As another example, certain embodiments of level shifter **1200** are operable when both Vcc-Vss and Vbst-Vx are as low as one volt, thereby potentially enabling operation at low

input voltages. Furthermore, the fact that level shifter **1200** uses differential signals, such as complementary current signals **1208**, **1210**, helps reject common mode transients between the V_{cc}/V_{ss} and V_{bst}/V_x domains.

Multiple instances of MPPT controller **302** can be electrically coupled together. For example, FIG. **13** illustrates an electric power system **1300** including N instances of MPPT controller **302** in a photovoltaic application, where N is an integer greater than one. In this document, specific instances of an item may be referred to by use of a numeral in parentheses (e.g., MPPT controller **302**(1)) while numerals without parentheses refer to any such item (e.g., MPPT controllers **302**).

The input port **308** of each MPPT controller **302** is electrically coupled to a respective photovoltaic device **1304** of a common photovoltaic module **1305**. Photovoltaic devices **1304** are, for example, single photovoltaic cells or groups of electrically interconnected photovoltaic cells. However, the configuration of photovoltaic devices **1304** can be varied without departing from the scope hereof. For example, in some alternate embodiments, photovoltaic devices **1304** are discrete photovoltaic devices and are not part of a common module. As another example, in some other embodiments, two or more photovoltaic devices **1304** have different configurations. A respective input capacitor **1324** is also electrically coupled across each input port **308**.

Output ports **314** of MPPT controllers **1302** are electrically coupled in series with a load **1306**. One or more output capacitors **1334** are electrically coupled across load **1306** and are shared by each of the N MPPT controllers **1302**. However, in some alternate embodiments, load **1306** contains significant capacitance and capacitors **1334** are therefore omitted. Additionally, in some other alternate embodiments, each MPPT controller **302** has a respective capacitor (not shown) electrically coupled across its output port **314**.

MPPT controllers **302** use interconnection inductance **1336** of an output circuit **1332** electrically coupling switching circuits **326** to load **1306** as energy storage inductance. Although this interconnection inductance is symbolically shown as a single element, it is actually distributed along a loop forming output circuit **1332**. Some alternate embodiments, however, include one or more discrete inductors (not shown) electrically coupled in series with output circuit **1332**. For example, each MPPT controller **302** is typically required to have a respective discrete inductor electrically coupled in series with its output port **314** in embodiments where each MPPT controller **302** has a respective capacitor electrically coupled across its output port **314**.

Each MPPT controller **302** essentially operates in the same manner as discussed with respect to electric power systems including a single MPPT controller **302** instance. For example, each MPPT controller **302** regulates a voltage V_{in} across its input port **308** to maximize power extracted from its respective photovoltaic device **304**. In some embodiments, MPPT controllers **302** operate out of phase with respect to each other to prevent constructive interference of transients resulting from switching circuit **326** operation.

MPPT controller **302** can be modified such that position of its control and freewheeling switching devices are swapped. For example, MPPT controller **302** could be modified such that switching device **330** is a control switching device and switching device **328** is a freewheeling device, thereby allowing the control switching device to be driven without a bootstrap circuit. As a result of this modification, output port **314** would be electrically coupled across switching device **328** instead of across switching device **330**.

Combinations of Features

Features described above as well as those claimed below may be combined in various ways without departing from the scope hereof. The following examples illustrate some possible combinations:

(A1) A maximum power point tracking controller may include an input port for electrically coupling to an electric power source, an output port for electrically coupling to a load, a control switching device, and a control subsystem. The control switching device may be adapted to repeatedly switch between its conductive and non-conductive states to transfer power from the input port to the output port. The control subsystem may be adapted to control switching of the control switching device to regulate a voltage across the input port, based at least in part on a signal representing current flowing out of the output port, to maximize a signal representing power out of the output port.

(A2) In the maximum power point tracking controller denoted as (A1), the control subsystem may be further adapted to control switching of the control switching device based partially on the signal representing current flowing out of the output port and a difference between the voltage across the input port and a reference voltage.

(A3) In the maximum power point tracking controller denoted as (A2), the control subsystem may be further adapted to vary a magnitude of the reference voltage to maximize the signal representing power out of the output port.

(A4) In either of the maximum power point tracking controllers denoted as (A2) or (A3), the control subsystem may be further adapted to control switching of the control switching device based partially on an error signal given by $-K_v \cdot (V_{in} - V_{ref}) + K_i \cdot I_o$, where K_v is a first scaling factor, K_i is a second factor, V_{in} is the voltage across the input port, V_{ref} is the reference voltage, and I_o is the signal representing current flowing out of the output port.

(A5) In any of the maximum power point tracking controllers denoted as (A2) through (A4), the control subsystem may include a multiplier adapted to determine the signal representing power out of the output port from a product of a scaled signal representing average voltage across the output port and a scaled signal representing average current flowing out of the output port.

(A6) In the maximum power point tracking controller denoted as (A5), the control subsystem may further include: (a) a voltage scaling subsystem adapted to generate the scaled signal representing average voltage across the output port by scaling a signal representing average voltage across the output power port to be within a first predetermined range; and (b) a current scaling subsystem adapted to generate the scaled signal representing average current flowing out of the output port by scaling a signal representing average current flowing out the output port to be within a second predetermined range.

(A7) In the maximum power point tracking controller denoted as (A6), the current scaling subsystem may be further adapted to prevent a magnitude of the scaled signal representing average current flowing out of the output port from falling below a minimum threshold value.

(A8) In the maximum power point tracking controller denoted as (A7), the current scaling subsystem may be further adapted to add a positive offset value to the scaled signal representing average current flowing out of the output port when the signal representing average current flowing out the output port is within a range of values.

(A9) In any of the maximum power point tracking controllers denoted as (A6) through (A8), the control subsystem may further include a current filter subsystem adapted to generate

the signal representing average current flowing out of the output port by filtering the signal representing current flowing out the output port.

(A10) In any of the maximum power point tracking controllers denoted as (A6) through (A10), the control subsystem may further include a voltage filter subsystem adapted to generate the signal representing average voltage across the output port by filtering a signal representing voltage across the output port.

(A11) In any of the maximum power point tracking controllers denoted as (A2) through (A10), the control subsystem may be further adapted to inhibit a reduction in the magnitude of the reference voltage when the voltage across the input port falls below a second threshold value.

(A12) In any of the maximum power point tracking controllers denoted as (A2) through (A10), the control subsystem may be further adapted to inhibit a reduction in the magnitude of the reference voltage when doing so would cause the voltage across the input port to fall below a third threshold value.

(A13) In any of the maximum power point tracking controllers denoted as (A2) through (A12), the control subsystem may be further adapted to inhibit an increase in the magnitude of the reference voltage when the voltage across the input port rises above a fourth threshold value.

(A14) In any of the maximum power point tracking controllers denoted as (A2) through (A13), the control subsystem may be further adapted to: (a) change the magnitude of the reference voltage by a first step size, to maximize the signal representing power out of the output port, when a command to control a duty cycle of the control switching device is below a fifth threshold value; and (b) change the magnitude of the reference voltage by a second step size, to maximize the signal representing power out of the output port, when a command to control a duty cycle of the control switching device is greater than or equal to a sixth threshold value; where the second step size is smaller than the first step size.

(A15) In the maximum power point tracking controller denoted as (A14), the fifth threshold value may be the same as the sixth threshold value.

(A16) In any of the maximum power point tracking controllers denoted as (A2) through (A15), the control subsystem may be further adapted to: (a) change the magnitude of the reference voltage by a third step size, to maximize the signal representing power out of the output port, when a difference in the signal representing power out of the output port between successive changes in magnitude of the reference voltage is below a seventh threshold value; and (b) change the magnitude of the reference voltage by a fourth step size, to maximize the signal representing power out of the output port, when a difference in the signal representing power out of the output port between successive changes in magnitude of the reference voltage is greater than or equal to a eighth threshold value; where the fourth step size is greater than the third step size.

(A17) In the maximum power point tracking controller denoted as (A16), the seventh threshold value may be the same as the eighth threshold value.

(A18) In any of the maximum power point tracking controllers denoted as (A2) through (A17), the control subsystem may be further adapted to: (a) change the magnitude of the reference voltage at a first rate, to maximize the signal representing power out of the output port, when a command to control a duty cycle of the control switching device is within a first range of values; and (b) change the magnitude of the reference voltage at a second rate, to maximize the signal representing power out of the output port, when the command

to control the duty cycle of the control switching device is within a second range of values; where the second rate is greater than the first rate.

(A19) In the maximum power point tracking controller denoted as (A18), the first range of values may represent a command that the duty cycle of the control switching device be between zero and one hundred percent, and the second range of values may represent a command that the duty cycle of the control switching device be less than zero or greater than one hundred percent.

(A20) In any of the maximum power point tracking controllers denoted as (A2) through (A19), the control subsystem may be further adapted to increase the magnitude of the reference voltage in response to the magnitude of the voltage across the input port falling below a ninth threshold value.

(A21) In any of the maximum power point tracking controllers denoted as (A2) through (A21), the control subsystem may be further adapted to set an initial magnitude of the reference voltage based at least partially on an initial value of the voltage across the input port, at start-up of the switching circuit.

(A22) In the maximum power point tracking controller denoted as (A21), the control subsystem may be further adapted to set the initial magnitude of the reference voltage to a fraction of the voltage across the input port, at start-up of the switching circuit.

(A23) In any of the maximum power point tracking controllers denoted as (A2) through (A22), the control subsystem may be further adapted to decrease the magnitude of the reference voltage in response to the signal representing current flowing out of the output port indicating that a magnitude of current flowing out of the output port has fallen below a tenth threshold level.

(A24) In the maximum power point tracking controller denoted as (A23), the control subsystem may be further adapted to operate the control switching device at a fixed duty cycle in response to the signal representing current flowing out of the output port indicating that a magnitude of current flowing out of the output port has fallen below an eleventh threshold level, where the eleventh threshold level is lower than the tenth threshold level.

(A25) In any of the maximum power point tracking controllers denoted as (A1) through (A24), the control switching device may be electrically coupled between a first terminal of the input port and a first terminal of the output port, and the maximum power point tracking controller may further include a freewheeling device electrically coupled between the first terminal of the output port and a second terminal of the output port, where the freewheeling device is adapted to provide a path for current flowing between the first and second terminals of the output port when the control switching device is in its non-conductive state.

(A26) In any of the maximum power point tracking controllers denoted as (A1) through (A25), the control switching device and the control subsystem may be part of a common integrated circuit.

(A27) In any of the maximum power point tracking controllers denoted as (A1) through (A26): (a) the control switching device may include a dynamically sized field effect transistor; (b) the maximum power point tracking controller may further include a current reconstructor subsystem adapted to generate the signal representing current flowing out of the output port, where the current reconstructor subsystem has a gain at least partially dependent on a size of the dynamically sized field effect transistor; and (c) the control subsystem may be adapted to decrease a size of the dynamically sized field effect transistor if a magnitude of the signal representing

current flowing out of the output port falls below a twelfth threshold value, thereby increasing the gain of the current reconstructor subsystem.

(B1) An electric power system may include an electric power source and a maximum power point tracking controller. The maximum power point tracking controller may include an input port for electrically coupled to the electric power source, an output port for electrically coupling to a load, a control switching device, and a control subsystem. The control switching device may be adapted to repeatedly switch power from the input port to the output port. The control subsystem may be adapted to control switching of the control switching device to regulate a voltage across the input port, based at least in part on a signal representing current flowing out of the output port, to maximize a signal representing power out of the output port.

(B2) In the electric power system denoted as (B1), the electric power source may include a photovoltaic device.

(B3) In the electric power system denoted as (B2), the photovoltaic device may include a plurality of interconnected photovoltaic cells.

(B4) In either of the electric power systems denoted as (B2) or (B3), the photovoltaic device may include a multi-junction photovoltaic cell.

(B5) In any of the electric power systems denoted as (B1) through (B4), the control subsystem may be adapted to control switching of the control switching device based partially on the signal representing current flowing out of the output port and a difference between the voltage across the input port and a reference voltage.

(B6) In the electric power system denoted as (B5), the control subsystem may be further adapted to vary a magnitude of the reference voltage to maximize the signal representing power out of the output port.

(B7) In either of the electric power systems denoted as (B5) or (B6) the control subsystem may be further adapted to control switching of the control switching device based partially on an error signal given by $-K_v \cdot (V_{in} - V_{ref}) + K_i \cdot I_o$, where K_v is a first scaling factor, K_i is a second scaling factor, V_{in} is the voltage across the input port, V_{ref} is the reference voltage, and I_o is the signal representing current flowing out of the output port.

(B8) In any of the electric power systems denoted as (B1) through (B7), the control switching device may be electrically coupled between a first terminal of the input port and a first terminal of the output port, and the maximum power point tracking controller may further include a freewheeling device electrically coupled between the first terminal of the output port and a second terminal of the output port, where the freewheeling device is adapted to provide a path for current flowing between the first and second terminals of the output port when the control switching device is in its non-conductive state.

(B9) In any of the electric power systems denoted as (B1) through (B8), the control subsystem may include a multiplier adapted to determine the signal representing power out of the output port from a product of a scaled signal representing average voltage across the output port and a scaled signal representing average current flowing out of the output port.

(B10) In the electric power system denoted as (B9), the control subsystem may be further adapted to prevent a magnitude of the scaled signal representing average current flowing out of the output port from falling below a minimum threshold value.

(B11) In any of the electric power systems denoted as (B1) through (B10), the control switching device and the control subsystem may be part of a common integrated circuit.

(B12) In the electric power system denoted as (B11), the common integrated circuit and the photovoltaic device may be co-packaged.

(B13) Any of the electric power systems denoted as (B1) through (B12) may further include one or more additional maximum power point tracking controllers electrically coupled in series with the output port and the load, where each additional maximum power point tracking controller is adapted to transfer power from a respective additional electric power source to the load.

(C1) A method for operating a maximum power point tracking controller including an input port for electrically coupled to an electric power source and an output port for electrically coupling to a load may include the steps of: (a) repeatedly switching a control switching device of the maximum power point tracking controller between its conductive and non-conductive states to transfer power from the input port to the output port; and (b) controlling switching of the control switching device, based at least in part on a signal representing current flowing out of the output port, to regulate a magnitude of a voltage across the input port such that a signal representing power out of the output port is maximized.

(C2) The method denoted as (C1) may further include controlling switching of the control switching device partially based on the signal representing current flowing out of the output port and a difference between the magnitude of the voltage across the input port and a reference voltage.

(C3) The method denoted as (C2) may further include varying a magnitude of the reference voltage to maximize the signal representing power out of the output port.

(C4) Either of the methods denoted as (C2) or (C3) may further include controlling switching of the control switching device partially based on an error signal given by $-K_v \cdot (V_{in} - V_{ref}) + K_i \cdot I_o$, where K_v is a first scaling factor, K_i is a second scaling factor, V_{in} is the voltage across the input port, V_{ref} is the reference voltage, and I_o is the signal representing current flowing out of the output port.

(C5) Any of the methods denoted as (C2) through (C4) may further include determining the signal representing power out of the output port by multiplying a signal representing average voltage across the output port by a signal representing average current flowing out of the output port, using a multiplier.

(C6) The method denoted as (C5) may further include filtering the signal representing current flowing out of the output port to generate the signal representing average current flowing out of the output port.

(C7) Either of the methods denoted as (C5) or (C6) may further include filtering a signal representing voltage across the output port to generate the signal representing average voltage across the output power port.

(C8) Any of the methods denoted as (C5) through (C7) may further include preventing a magnitude of the signal representing average current flowing out of the output port from falling below a minimum threshold value.

(C9) Any of the methods denoted as (C2) through (C8) may further include: (a) storing a first sample of the signal representing power out of the output port when a duty cycle of the control switching device is one hundred percent duty cycle; (b) decreasing the magnitude of the reference voltage by a first amount; (c) storing a second sample of the signal representing power out of the output port, after the step of decreasing the magnitude of the reference voltage by the first amount;

(d) comparing the first sample of the signal representing power out of the output port to the second sample of the signal representing power out of the output port; (e) increasing the magnitude of the reference voltage when the first sample of the signal representing power out of the output port is greater than the second sample of the signal representing power out of the output port; and (f) decreasing the magnitude of the reference voltage when the second sample of the signal representing power out of the output port is greater than the first sample of the signal representing power out of the output port.

(C10) Any of the methods denoted as (C2) through (C9) may further include inhibiting a reduction in the magnitude of the reference voltage when the voltage across the input port falls below a second threshold value.

(C11) Any of the methods denoted as (C2) through (C10) may further include inhibiting an increase in the magnitude of the reference voltage when the voltage across the input port rises above a third threshold value.

(C12) Any of the methods denoted as (C2) through (C11) may further include: (a) changing the magnitude of the reference voltage by a first step size, to maximize the signal representing power out of the output port, when a command to control a duty cycle of the control switching device is below a fourth threshold value; and (b) changing the magnitude of the reference voltage by a second step size, to maximize the signal representing power out of the output port, when a command to control a duty cycle of the control switching device is greater than or equal to a fifth threshold value; where the second step size is smaller than the first step size.

(C13) Any of the methods denoted as (C2) through (C11) may further include: (a) changing the magnitude of the reference voltage at a first rate, to maximize the signal representing power out of the output port, when a command to control a duty cycle of the control switching device is within a first range of values; and (b) changing the magnitude of the reference voltage at a second rate, to maximize the signal representing power out of the output port, when the command to control the duty cycle of the control switching device is within a second range of values; where the second rate being greater than the first rate.

(C14) In the method denoted as (C13), the first range of values may represent that the duty cycle of the control switching device is commanded to be between zero and one hundred percent, and the second range of values may represent that the duty cycle of the control switching device is commanded to be less than zero or greater than one hundred percent.

(C15) Any of the methods denoted as (C2) through (C14) may further include increasing the magnitude of the reference voltage in response to the magnitude of the voltage across the input port falling below a sixth threshold value.

(C16) Any of the methods denoted as (C2) through (C15) may further include setting an initial magnitude of the reference voltage based at least partially on an initial value of the voltage across the input port, at start-up of the switching circuit.

(C17) The method denoted as (C16) may further include setting the initial magnitude of the reference voltage to a fraction of the voltage across the input port, at start-up of the switching circuit.

(C18) Any of the methods denoted as (C2) through (C17) may further include decreasing the magnitude of the reference voltage in response to a magnitude of current flowing out of the output port falling below a seventh threshold level.

(C19) The method denoted as (C18) may further include operating the control switching device at a fixed duty cycle in response to a magnitude of current flowing out of the output

port falling below a eighth threshold level, where the eighth threshold level is lower than the seventh threshold level.

(C20) Any of the methods denoted as (C1) through (C19) may further include: (a) generating the signal representing current flowing out of the output port using a current reconstructor subsystem; and (b) decreasing a size of a dynamically sized field effect transistor of the control switching device when a magnitude of the signal representing current flowing out of the output port falls below a ninth threshold value, thereby increasing a gain of the current reconstructor subsystem.

(D1) An electronic filter may include: (a) an integrator subsystem adapted to operate in a bipolar domain to filter an alternating current component of an input signal; and (b) transconductance circuitry adapted to operate in a unipolar domain to generate an output current signal proportional to an average value of the input current signal.

(D2) In the electronic filter denoted as (D1): the integrator subsystem may be adapted to generate an integrator signal representing the average value of the input current signal; and (b) the transconductance circuitry may include a first transconductance amplifier adapted to generate the output current signal, from the integrator signal.

(D3) In the electronic filter denoted as (D2), the transconductance circuitry may further include a second transconductance amplifier adapted to generate a direct current component of the input current signal, from the integrator signal.

(D4) In any of the electronic filters denoted as (D1) through (D3), the integrator subsystem may include: (a) an integrator having an inverting input terminal and a non-inverting input terminal, and (b) a resistive device electrically coupled across the input terminals of integrator; where the non-inverting input terminal of the integrator is electrically coupled to a reference node of the electronic filter via a voltage source, the inverting input terminal of the integrator is electrically coupled to a first node, and the electronic filter is arranged such that the input current signal flows out of the first node.

(E1) A signal scaling system may include (a) a transconductance subsystem adapted to convert an input voltage signal to an output current signal, the transconductance subsystem including a programmable resistor adapted to set a gain of the transconductance subsystem; and (b) control logic adapted to set a resistance of the programmable resistor to adjust the gain of the transconductance subsystem such that a magnitude of the output current signal is at least as large as a first threshold value.

(E2) In the signal scaling system denoted as (E1) the transconductance subsystem may further include: (a) a transistor electrically coupled to the programmable resistor; and (b) an amplifier adapted to control the transistor to regulate a voltage across the programmable resistor in response to the input voltage signal.

(E3) In either of the signal scaling systems denoted as (E1) or (E2), the control logic may be further adapted to set a gain of the transconductance subsystem to a minimum value in response to a first external signal.

(E4) In any of the signal scaling systems denoted as (E1) through (E3), the control logic may be further adapted to increment the gain of the transconductance subsystem in response to a second external signal, until the magnitude of the output current signal is at least as large as the first threshold value.

(E5) In any of the signal scaling systems denoted as (E1) through (E4), the control logic may be further adapted to detect when the magnitude of the output current signal exceeds a second threshold value, where the second threshold value is greater than the first threshold value.

(E6) In the signal scaling system denoted as (E5), the control logic may be further adapted to generate a signal indicating that the magnitude of the output current signal exceeds the second threshold value.

(E7) In any of the signal scaling systems denoted as (E1) through (E6), the transconductance system may further include a current mirror adapted to generate the output current signal in response to current flowing through the programmable resistor.

(F1) A signal level shifter for shifting complementary input voltage signals in a first power supply domain to complementary output voltage signals in a second power supply domain may include: (a) a transconductance stage in the first power supply domain adapted to generate complementary current signals in response to the complementary input voltage signals; and (b) a load circuit in the second power supply domain adapted to generate the complementary output voltage signals in response to the complementary current signals, where the load circuit includes first and second inverter circuits adapted to generate the complementary output voltage signals in response to the complementary current signals.

(F2) In the signal level shifter denoted as (F1): a high side rail of the first inverter circuit may be electrically coupled to a high side rail of the second power supply domain by a first transistor; a high side rail of the second inverter circuit may be electrically coupled to the high side rail of the second power supply domain by a second transistor; and the first and second transistors may be cross-coupled.

(F3) In the signal level shifter denoted as (F2), each of the inverter circuits may include: (a) a high side transistor electrically coupled between the high side rail of the inverter circuit and an output node of the inverter circuit; and (b) a low side transistor electrically coupled between the output node of the inverter circuit and a reference rail of the second power supply domain; where the high side transistor is operable to pull the output node of the inverter circuit up to at least fifty percent of an electrical potential of the high side rail of the inverter, with respect to the reference rail of the second power supply domain, when the low side transistor is in its conductive state.

(F4) In either of the signal level shifters denoted as (F2) or (F3), the transconductance stage may be operable to drive current into the high side rails of the first and second inverter circuits, when an electrical potential of a reference rail of the second power supply domain is below an electrical potential of a reference rail of the first power supply domain.

(G1) A system for determining a signal representing power in a maximum power point tracking (MPPT) controller may include: (a) a voltage filter subsystem adapted to generate a signal representing average voltage across an output port of the MPPT controller by filtering a signal representing voltage across the output port; (b) a current filter subsystem adapted to generate a signal representing average current flowing out of the output port by filtering a signal representing current flowing out the output port; (c) a voltage scaling subsystem adapted to generate a scaled signal representing average voltage across the output port by scaling the signal representing average voltage across the output port to be within a first predetermined range; (d) a current scaling subsystem adapted to generate a scaled signal representing average current flowing out of the output port by scaling the signal representing average current flowing out the output port to be within a second predetermined range; and (e) a multiplier adapted to determine the signal representing power from a product of the scaled signal representing average voltage across the output port and the scaled signal representing average current flowing out of the output port.

(G2) In the system denoted as (G1), the multiplier may include: (a) a first input port adapted to receive the scaled signal representing average voltage across the output port; (b) a second input port adapted to receive the scaled signal representing average current flowing out of the output port; (c) an output port adapted to provide the signal representing power; (d) a first field effect transistor electrically coupled in series with the first input port; (e) a second field effect transistor electrically coupled in series with the second input port; (f) a third field effect transistor electrically coupled in series with the output port; and (g) control circuitry adapted to control each of the first, second, and third field effect transistors such that a magnitude of current flowing into the output port is proportional to a product of (1) a magnitude of current flowing into the first input port, and (2) a magnitude of current flowing into the second input port.

(G3) In the system denoted as (G2), a gate of the first field effect transistor may be electrically coupled to a gate of the third field effect transistor.

(G4) The system denoted as (G3) may further include: (a) fourth and fifth field effect transistors forming a current mirror configured such that a magnitude of a drain-to-source current flowing through the fifth field effect transistor is equal to I_{ref} , and a magnitude of a drain-to-source current flowing through the fourth field effect transistor is equal to I_{ref}/m ; and (b) a first amplifier adapted to control the gate of the first field effect transistor such that a voltage across the first field effect transistor is equal to a voltage across the fourth field effect transistor.

(G5) In the system denoted as (G4), a gate of the second field effect transistor may be electrically coupled to a gate of the fourth field effect transistor and a gate of the fifth field effect transistor.

(G6) In either of the systems denoted as (G4) or (G5), the second field effect transistor may have a channel resistance equal to R/m , and the fourth and fifth field effect transistors may each have a channel resistance equal to R , when the second, fourth, and fifth transistors are driven by a common gate-to-source voltage.

(G7) Any of the systems denoted as (G2) through (G6) may further include a second amplifier and a sixth transistor configured to control the magnitude of current flowing into the output port such that a voltage across the second field effect transistor is equal to a voltage across the third field effect transistor.

(G8) In any of the systems denoted as (G1) through (G7), the current scaling subsystem may include: (a) a transconductance subsystem adapted to convert the signal representing average current flowing out the output port to the scaled signal representing average current flowing out of the output port, the transconductance subsystem including a programmable resistor adapted to set a gain of the transconductance subsystem; and (b) control logic adapted to set a resistance of the programmable resistor to adjust the gain of the transconductance subsystem such that a magnitude of the scaled signal representing average current flowing out of the output port is at least as large as a first threshold value.

(G9) In the system denoted as (G8), the transconductance subsystem may further include: (a) a transistor electrically coupled to the programmable resistor; and (b) an amplifier adapted to control the transistor to regulate a voltage across the programmable resistor in response to the signal representing average current flowing out of the output port.

(G10) In either of the systems denoted as (G8) or (G9), the control logic may be further adapted to set a gain of the transconductance subsystem to a minimum value in response to a first external signal.

31

(G11) In any of the systems denoted as (G8) through (G10), the control logic may be further adapted to increment the gain of the transconductance subsystem in response to a second external signal, until the magnitude of the scaled signal representing current flowing out of the output port is at least as large as the first threshold value.

(G12) In any of the systems denoted as (G8) through (G11), the transconductance subsystem may further include a current mirror adapted to generate the scaled signal representing average current flowing out of the output port in response to current flowing through the programmable resistor.

(G13) In any of the systems denoted as (G1) through (G12), the current filter subsystem may include: (a) an integrator subsystem adapted to operate in a bipolar domain to filter an alternating current component of the signal representing current flowing out the output port; and (b) transconductance circuitry adapted to operate in a unipolar domain to generate the signal representing average current flowing out of the output port from an average value of the signal representing current flowing out the output port.

(G14) In the system denoted as (G13): the integrator subsystem may be adapted to generate an integrator signal representing the average value of the signal representing current flowing out the output port; and the transconductance circuitry may include a first transconductance amplifier adapted to generate the signal representing average current flowing out of the output port, from the integrator signal.

(G15) In the system denoted as (G14), the transconductance circuitry may further include a second transconductance amplifier adapted to generate a direct current component of the signal representing current flowing out the output port, from the integrator signal.

(G16) In any of the systems denoted as (G13) through (G15), the integrator subsystem may include: (a) an integrator having an inverting input terminal and a non-inverting input terminal; and (b) a resistive device electrically coupled across the input terminals of integrator; the non-inverting input terminal of the integrator being electrically coupled to a reference node via a voltage source, the inverting input terminal of the integrator being electrically coupled to a first node, and the current filter subsystem arranged such that the signal representing current flowing out the output port flows out of the first node.

(H1) A multiplier may include: (a) a first and a second input port; (b) an output port; (c) a first field effect transistor electrically coupled in series with the first input port; (d) a second field effect transistor electrically coupled in series with the second input port; (e) a third field effect transistor electrically coupled in series with the output port; and (f) control circuitry adapted to control each of the first, second, and third field effect transistors such that a magnitude of current flowing into the output port is proportional to a product of (1) a magnitude of current flowing into the first input port, and (2) a magnitude of current flowing into the second input port.

(H2) In the multiplier denoted as (H1), a gate of the first field effect transistor may be electrically coupled to a gate of the third field effect transistor.

(H3) Either of the multipliers denoted as (H1) or (H2) may further include: (a) fourth and fifth field effect transistors forming a current mirror configured such that a magnitude of a drain-to-source current flowing through the fifth field effect transistor is equal to I_{ref} , and a magnitude of a drain-to-source current flowing through the fourth field effect transistor is equal to I_{ref}/m ; and (b) a first amplifier adapted to control the gate of the first field effect transistor such that a voltage across the first field effect transistor is equal to a voltage across the fourth field effect transistor.

32

(H4) In the multiplier denoted as (H3), a gate of the second field effect transistor may be electrically coupled to a gate of the fourth field effect transistor and a gate of the fifth field effect transistor.

(H5) In either of the multipliers denoted as (H3) or (H4), the second field effect transistor may have a channel resistance equal to R/m , and the fourth and fifth field effect transistors each may have a channel resistance equal to R , when the second, fourth, and fifth transistors are driven by a common gate-to-source voltage.

(H6) Any of the multipliers denoted as (H1) through (H5) may further include a second amplifier and a sixth transistor configured to control the magnitude of current flowing into the output port such that a voltage across the second field effect transistor is equal to a voltage across the third field effect transistor.

Changes may be made in the above methods and systems without departing from the scope hereof. For example, N-channel field effect transistors could be replaced with P-channel field effect transistors, or vice versa, with appropriate changes to associated circuitry. As another example, field effect transistors could be replaced with bipolar junction transistors, with appropriate changes to associated circuitry. It should thus be noted that the matter contained in the above description and shown in the accompanying drawings should be interpreted as illustrative and not in a limiting sense. The following claims are intended to cover generic and specific features described herein, as well as all statements of the scope of the present method and system, which, as a matter of language, might be said to fall therebetween.

What is claimed is:

1. A maximum power point tracking controller, comprising:

an input port for electrically coupling to an electric power source;

an output port for electrically coupling to a load;

a control switching device adapted to repeatedly switch between conductive and non-conductive states to transfer power from the input port to the output port; and

a control subsystem adapted to control switching of the control switching device to regulate a voltage across the input port, based at least in part on a signal representing current flowing out of the output port, to maximize a signal representing power out of the output port;

the control subsystem further adapted to:

control switching of the control switching device based partially on the signal representing current flowing out of the output port and a difference between the voltage across the input port and a reference voltage, vary a magnitude of the reference voltage to maximize the signal representing power out of the output port, and

control switching of the control switching device based partially on an error signal given by $-K_v \cdot (V_{in} - V_{ref}) + K_i \cdot I_o$, where K_v is a first scaling factor, K_i is a second scaling factor, V_{in} is the voltage across the input port, V_{ref} is the reference voltage, and I_o is the signal representing current flowing out of the output port.

2. The maximum power point tracking controller of claim 1, the control switching device being electrically coupled between a first terminal of the input port and a first terminal of the output port, the maximum power point tracking controller further comprising a freewheeling device electrically coupled between the first terminal of the output port and a second terminal of the output port, the freewheeling device adapted to provide a path for current flowing between the first and

33

second terminals of the output port when the control switching device is in its non-conductive state.

3. The maximum power point tracking controller of claim 2, the control subsystem comprising a multiplier adapted to determine the signal representing power out of the output port from a product of a scaled signal representing average voltage across the output port and a scaled signal representing average current flowing out of the output port.

4. The maximum power point tracking controller of claim 3, the control subsystem further comprising:

a voltage scaling subsystem adapted to generate the scaled signal representing average voltage across the output port by scaling a signal representing average voltage across the output power-port to be within a first predetermined range; and

a current scaling subsystem adapted to generate the scaled signal representing average current flowing out of the output port by scaling a signal representing average current flowing out the output port to be within a second predetermined range.

5. The maximum power point tracking controller of claim 4, the current scaling subsystem further adapted to prevent a magnitude of the scaled signal representing average current flowing out of the output port from falling below a minimum threshold value.

6. The maximum power point tracking controller of claim 5, the current scaling subsystem further adapted to add a positive offset value to the scaled signal representing average current flowing out of the output port when the signal representing average current flowing out the output port is within a first range of values.

7. The maximum power point tracking controller of claim 4, the control subsystem further comprising a current filter subsystem adapted to generate the signal representing average current flowing out of the output port by filtering the signal representing current flowing out the output port.

8. The maximum power point tracking controller of claim 7, the control subsystem further comprising a voltage filter subsystem adapted to generate the signal representing average voltage across the output port by filtering a signal representing voltage across the output port.

9. The maximum power point tracking controller of claim 1, the control subsystem further adapted to inhibit a reduction in the magnitude of the reference voltage when the voltage across the input port falls below a threshold value.

10. The maximum power point tracking controller of claim 1, the control subsystem further adapted to inhibit a reduction in the magnitude of the reference voltage when doing so would cause the voltage across the input port to fall below a threshold value.

11. The maximum power point tracking controller of claim 1, the control subsystem further adapted to inhibit an increase in the magnitude of the reference voltage when the voltage across the input port rises above a threshold value.

12. The maximum power point tracking controller of claim 1, the control subsystem further adapted to:

change the magnitude of the reference voltage by a first step size, to maximize the signal representing power out of the output port, when a command to control a duty cycle of the control switching device is below a first threshold value; and

change the magnitude of the reference voltage by a second step size, to maximize the signal representing power out of the output port, when a command to control a duty cycle of the control switching device is greater than or equal to a second threshold value;

the second step size being smaller than the first step size.

34

13. The maximum power point tracking controller of claim 12, the first threshold value being the same as the second threshold value.

14. The maximum power point tracking controller of claim 1, the control subsystem further adapted to:

change the magnitude of the reference voltage by a first step size, to maximize the signal representing power out of the output port, when a difference in the signal representing power out of the output port between successive changes in magnitude of the reference voltage is below a first threshold value; and

change the magnitude of the reference voltage by a second step size, to maximize the signal representing power out of the output port, when a difference in the signal representing power out of the output port between successive changes in magnitude of the reference voltage is greater than or equal to a second threshold value;

the second step size being greater than the first step size.

15. The maximum power point tracking controller of claim 14, the first threshold value being the same as the second threshold value.

16. The maximum power point tracking controller of claim 1, the control subsystem further adapted to:

change the magnitude of the reference voltage at a first rate, to maximize the signal representing power out of the output port, when a command to control a duty cycle of the control switching device is within a first range of values; and

change the magnitude of the reference voltage at a second rate, to maximize the signal representing power out of the output port, when the command to control the duty cycle of the control switching device is within a second range of values;

the second rate being greater than the first rate.

17. The maximum power point tracking controller of claim 16, the first range of values representing a command that the duty cycle of the control switching device be between zero and one hundred percent, and the second range of values representing a command that the duty cycle of the control switching device be less than zero or greater than one hundred percent.

18. The maximum power point tracking controller of claim 1, the control subsystem further adapted to increase the magnitude of the reference voltage in response to the magnitude of the voltage across the input port falling below a threshold value.

19. The maximum power point tracking controller of claim 1, the control subsystem further adapted to set an initial magnitude of the reference voltage based at least partially on an initial value of the voltage across the input port, at start-up of the switching circuit.

20. The maximum power point tracking controller of claim 19, the control subsystem further adapted to set the initial magnitude of the reference voltage to a fraction of the voltage across the input port, at start-up of the switching circuit.

21. The maximum power point tracking controller of claim 1, the control subsystem further adapted to decrease the magnitude of the reference voltage in response to the signal representing current flowing out of the output port indicating that a magnitude of current flowing out of the output port has fallen below a first threshold level.

22. The maximum power point tracking controller of claim 21, the control subsystem further adapted to operate the control switching device at a fixed duty cycle in response to the signal representing current flowing out of the output port indicating that a magnitude of current flowing out of the

35

output port has fallen below a second threshold level, where the second threshold level is lower than the first threshold level.

23. The maximum power point tracking controller of claim 1, the control switching device and the control subsystem being part of a common integrated circuit.

24. The maximum power point tracking controller of claim 1, wherein:

the control switching device comprises a dynamically sized field effect transistor;

the maximum power point tracking controller further comprises a current reconstructor subsystem adapted to generate the signal representing current flowing out of the output port, the current reconstructor subsystem having a gain at least partially dependent on a size of the dynamically sized field effect transistor; and

the control subsystem is adapted to decrease a size of the dynamically sized field effect transistor if a magnitude of the signal representing current flowing out of the output port falls below a threshold value, thereby increasing the gain of the current reconstructor subsystem.

25. An electric power system, comprising:

an electric power source; and

a maximum power point tracking controller, including:

an input port electrically coupled to the electric power source,

an output port for electrically coupling to a load,

a control switching device adapted to repeatedly switch between conductive and non-conductive states to transfer power from the electric power source to the output port, and

a control subsystem adapted to control switching of the control switching device to regulate a voltage across the input port, based at least in part on a signal representing current flowing out of the output port, to maximize a signal representing power out of the output port;

the control subsystem further adapted to:

control switching of the control switching device based partially on the signal representing current flowing out of the output port and a difference between the voltage across the input port and a reference voltage, vary a magnitude of the reference voltage to maximize the signal representing power out of the output port, and

control switching of the control switching device based partially on an error signal given by $-K_v \cdot (V_{in} - V_{ref}) + K_i \cdot I_o$, where K_v is a first scaling factor, K_i is a second scaling factor, V_{in} is the voltage across the input port, V_{ref} is the reference voltage, and I_o is the signal representing current flowing out of the output port.

26. The electric power system of claim 25, the electric power source comprising a photovoltaic device.

27. The electric power system of claim 26, the photovoltaic device comprising a plurality of interconnected photovoltaic cells.

28. The electric power system of claim 26, the photovoltaic device comprising a multi-junction photovoltaic cell.

29. The electric power system of claim 25, the control switching device being electrically coupled between a first terminal of the input port and a first terminal of the output port, the maximum power point tracking controller further comprising a freewheeling device electrically coupled between the first terminal of the output port and a second terminal of the output port, the freewheeling device adapted

36

to provide a path for current flowing between the first and second terminals of the output port when the control switching device is in its non-conductive state.

30. The electric power system of claim 29, the control subsystem comprising a multiplier adapted to determine the signal representing power out of the output port from a product of a scaled signal representing average voltage across the output port and a scaled signal representing average current flowing out of the output port.

31. The electric power system of claim 30, the control subsystem further adapted to prevent a magnitude of the scaled signal representing average current flowing out of the output port from falling below a minimum threshold value.

32. The electric power system of claim 26, the control switching device and the control subsystem being part of a common integrated circuit.

33. The electric power system of claim 32, the common integrated circuit and the photovoltaic device being co-packaged.

34. The electric power system of claim 25, further comprising one or more additional maximum power point tracking controllers electrically coupled in series with the output port and the load, each additional maximum power point tracking controller adapted to transfer power from a respective additional electric power source to the load.

35. A method for operating a maximum power point tracking controller including an input port for electrically coupled to an electric power source and an output port for electrically coupling to a load, comprising the steps of:

repeatedly switching a control switching device of the maximum power point tracking controller between conductive and non-conductive states to transfer power from the input port to the output port;

controlling switching of the control switching device, based at least in part on a signal representing current flowing out of the output port, to regulate a magnitude of a voltage across the input port such that a signal representing power out of the output port is maximized;

controlling switching of the control switching device partially based on the signal representing current flowing out of the output port and a difference between the magnitude of the voltage across the input port and a reference voltage;

varying a magnitude of the reference voltage to maximize the signal representing power out of the output port; and controlling switching of the control switching device partially based on an error signal given by $-K_v \cdot (V_{in} - V_{ref}) + K_i \cdot I_o$, where K_v is a first scaling factor, K_i is a second scaling factor, V_{in} is the voltage across the input port, V_{ref} is the reference voltage, and I_o is the signal representing current flowing out of the output port.

36. The method of claim 35, further comprising determining the signal representing power out of the output port by multiplying a signal representing average voltage across the output port by a signal representing average current flowing out of the output port, using a multiplier.

37. The method of claim 36, further comprising filtering the signal representing current flowing out of the output port to generate the signal representing average current flowing out of the output port.

38. The method of claim 37, further comprising filtering a signal representing voltage across the output port to generate the signal representing average voltage across the output power port.

37

39. The method of claim 38, further comprising preventing a magnitude of the signal representing average current flowing out of the output port from falling below a minimum threshold value.

40. The method of claim 35, further comprising:

storing a first sample of the signal representing power out of the output port when a duty cycle of the control switching device is one hundred percent duty cycle;

decreasing the magnitude of the reference voltage by a first amount;

storing a second sample of the signal representing power out of the output port, after the step of decreasing the magnitude of the reference voltage by the first amount;

comparing the first sample of the signal representing power out of the output port to the second sample of the signal representing power out of the output port;

increasing the magnitude of the reference voltage when the first sample of the signal representing power out of the output port is greater than the second sample of the signal representing power out of the output port; and

decreasing the magnitude of the reference voltage when the second sample of the signal representing power out of the output port is greater than the first sample of the signal representing power out of the output port.

41. The method of claim 35, further comprising inhibiting a reduction in the magnitude of the reference voltage when the voltage across the input port falls below a threshold value.

42. The method of claim 35, further comprising inhibiting an increase in the magnitude of the reference voltage when the voltage across the input port rises above a threshold value.

43. The method of claim 35, further comprising:

changing the magnitude of the reference voltage by a first step size, to maximize the signal representing power out of the output port, when a command to control a duty cycle of the control switching device is below a first threshold value; and

changing the magnitude of the reference voltage by a second step size, to maximize the signal representing power out of the output port, when a command to control a duty cycle of the control switching device is greater than or equal to a second threshold value;

the second step size being smaller than the first step size.

44. The method of claim 35, further comprising:

changing the magnitude of the reference voltage at a first rate, to maximize the signal representing power out of

38

the output port, when a command to control a duty cycle of the control switching device is within a first range of values; and

changing the magnitude of the reference voltage at a second rate, to maximize the signal representing power out of the output port, when the command to control the duty cycle of the control switching device is within a second range of values;

the second rate being greater than the first rate.

45. The method of claim 44, the first range of values representing that the duty cycle of the control switching device is commanded to be between zero and one hundred percent, and the second range of values representing that the duty cycle of the control switching device is commanded to be less than zero or greater than one hundred percent.

46. The method of claim 35, further comprising increasing the magnitude of the reference voltage in response to the magnitude of the voltage across the input port falling below a threshold value.

47. The method of claim 35, further comprising setting an initial magnitude of the reference voltage based at least partially on an initial value of the voltage across the input port, at start-up of the switching circuit.

48. The method of claim 47, further comprising setting the initial magnitude of the reference voltage to a fraction of the voltage across the input port, at start-up of the switching circuit.

49. The method of claim 35, further comprising decreasing the magnitude of the reference voltage in response to a magnitude of current flowing out of the output port falling below a first threshold level.

50. The method of claim 49, further comprising operating the control switching device at a fixed duty cycle in response to a magnitude of current flowing out of the output port falling below a second threshold level, where the second threshold level is lower than the first threshold level.

51. The method of claim 35, further comprising:

generating the signal representing current flowing out of the output port using a current reconstructor subsystem; and

decreasing a size of a dynamically sized field effect transistor of the control switching device when a magnitude of the signal representing current flowing out of the output port falls below a threshold value, thereby increasing a gain of the current reconstructor subsystem.
